# SUGARBEET RESEARCH

1993 REPORT

## FOREWARD

SUGARBEET RESEARCH is an annual compilation of progress reports concerning research by Agricultural Research Service investigators and cooperators who are engaged in sugar beet variety and production research. The report has been assembled and reproduced at the expense of the Beet Sugar Development Foundation, and is for the sole use of its members and the cooperators. Much of the data has not been sufficiently confirmed to justify general release and interpretations may be modified with additional experimentation. The report is not intended for publication and should not be used for cited reference nor quoted in publicity or advertising. Reproduction of any portion of the material contained herein will not be permitted without the specific consent of the contributor and the Beet Sugar Development Foundation.

The report presents results of investigations strengthened by contributions received under Cooperative Agreements between Agricultural Research Service, U.S. Department of Agriculture, and the Beet Sugar Development Foundation; the California Beet Growers Association; and the Sugarbeet Research and Education Board of Minnesota and North Dakota.

Trade names occur in this report solely to provide specific information and do not signify endorsement by the U.S. Department of Agriculture or the Beet Sugar Development Foundation.

BLUA, M.J., T.M. PERRING, G.S. NUESSELY, J.E. DUFFUS, and N.C. TOSCANO. Impact of cropping patterns on Bemisia tabaci and LIYV. Environmental Entomology (In press). 1994.

The sweetpotato whitefly, *Bemisia tabaci* (Gennadius), was trapped throughout the southern desert agricultural region of California during two consecutive growing seasons. Trap data revealed changes in whitefly population densities that provide insight into the epidemiology of lettuce infectious yellows virus (LIYV) in fall melon and lettuce. Whitefly abundance increased rapidly from July to September in cotton. During this period, there were significant correlations between the number of cotton fields in a region and the number of whiteflies trapped in that region. Beginning in August and September, whitefly densities increased in melon, and the proportion of viruliferous whiteflies increased in cotton and melon. After the defoliation of cotton was initiated in September, whiteflies migrated to melons, which not only served as their host but also as a reservoir for LIYV. In October and November high numbers of viruliferous whiteflies were found in melon and lettuce. As melons were harvested and the fields dried, viruliferous whiteflies migrated to newly emerged lettuce.

CAMPBELL, B.C., J.E. DUFFUS, and P. BAUMAN. Determining whitefly species. Science 261:1333-1334. 1993.

The statement in the report by T. M. Perring et al. that the "superbug" is not a strain of the sweetpotato whitefly, *Bemisia tabaci* (Gennadius), but a new species, seems premature. When more than 25 pairs of males and females of both strains were placed together, interstrain mating resulted in the production of viable, hybrid females. Field collections made in the Imperial Valley of California in 1992 revealed that feral populations of the two strains had interbred. Hybrid whiteflies that had fixed (not induced) esterase loci from both "A" and "B" strain parents were clearly identified.

Perring et al. used single primer polymerase chain reaction amplification (RAPD-PCR) and found that genetic differences between the strains were at a "species" level, but RAPD-PCR fragments have revealed only arbitrary differences between the DNAs. "Genetic distances" of a size similar to those between *B. tabaci* strains are likely to be observed if either strain is compared to RAPD-PCR fragments generated from any number of randomly selected taxa (for example, another whitefly strain or species, dogs, or nematodes). The RAPD-PCR results in the report by Perring et al. are of potential diagnostic value, but of little phylogenetic utility.

When one of us (B.C.C.) compared more than 2000 nucleotides of genes in the ribosomal RNA (rRNA) transcript from *B. tabaci*, which included three variable expansion regions, the rDNA in those strains was identical. Sequences of 28S rDNA D2 expansion regions (550 nucleotides) have been found to be identical in the *B. tabaci* strains, whereas 40 nucleotide substitutions have been found in ash and greenhouse whiteflies. The D2 expansion region has been used to deduce phylogenies of subgenera and sibling species of *Drosophila*. Whiteflies also have uncommonly elongated ( $\approx 2450$  nucleotides) 18S rDNAs. This extra length stems from two internal, variable expansion regions (8). The 18S rDNA of the two *B. tabaci* strains has been found to be identical, whereas 60 to more than 100 nucleotide substitutions have been found in ash, iris, and greenhouse whiteflies. Sternorrhynchs (for example, aphids and whiteflies) have maternally heritable, procaryotic endosymbionts. An earlier study of endosymbiont 16S rDNA found that aphid endosymbiosis resulted from a singular infection of a primordial ancestor during the Triassic. Since that time, aphids and their endosymbionts have cospeciated, resulting in congruent phylogenies. Whitefly endosymbiosis follows a similar congruency, wherein endosymbiont 16S rDNA distinguishes whitefly species. Both strains of *B. tabaci* have two endosymbionts. The nucleotide sequences of 16S rDNAs ( $\approx 1600$  nucleotides each) of the respective endosymbionts have been found to be identical in the *B. tabaci* strains, whereas 70 nucleotide substitutions have been found in greenhouse and ash whiteflies. In summary, our mating and phylogenetic studies do not support the conclusion of Perring et al. that the "superbug" is a new species of whitefly.

DUFFUS, J.E., H.Y. LIU, and S. COHEN. Partial characterization of a new closterovirus, the causal agent of cucurbit yellow stunting disorder. Pg. in Sweetpotato Whitefly: 1994 Supplement to the Five-year Plan, U.S. Dept. Agr. ARS No. 112. (In press). 1994

Whitefly-transmitted yellowing viruses of cucurbits are causing severe economic losses throughout the world. In western USA lettuce infectious yellows (LIYV), vectored by *Bemisia tabaci*, caused large losses to cucurbits, lettuce and sugarbeet. In the USA, Europe, Asia and the Mediterranean region beet pseudo yellow virus (BPYV), vectored by *Trialeurodes vaporariorum*, causes major losses in controlled environments and outdoors in warmer regions. In the early 1980's a yellowing and stunting disorder of cucurbits was noticed in the middle east. On the basis of observations and limited serological studies this disease appeared to be distinct from LIYV and BPYV.

This virus, herein named Cucurbit yellow stunting disorder virus (CYSDV), is transmitted by the sweetpotato whitefly (*Bemisia tabaci*) in a semipersistent manner. The virus appears to have

a narrow host range, mainly in the Cucurbitaceae. The virus can cause economically significant losses on melons and cucumbers. The virus has been purified by differential centrifugation. Purified preparations contained long, flexuous particles 12 x 1200 nm. The host range, insect transmission and serology clearly distinguish CYSDV from previously described viruses.

DUFFUS, J.E., H.Y. LIU, and G.C. WISLER. A new closterovirus of tomato in southern California transmitted by the greenhouse whitefly (*Trialeurodes vaporariorum*). Phytopathology (In press). 1994.

A previously undescribed virus disease of tomato was found in the Orange County area of southern California. Affected tomato plants exhibited interveinal yellowing, necrosis and severe yield losses. The disease affected virtually 100% of the crop in the Irvine hills and valley region. The outbreak was associated with the occurrence of high populations of the greenhouse whitefly, *Trialeurodes vaporariorum* (Westwood). Leaf dips showed flexuous filamentous particles of variable length similar to closteroviruses. The virus was transmitted by *T. vaporariorum* but not by either the A or B biotypes of *Bemisia tabaci* (sweetpotato whitefly). Further characterization by protein and RNA analysis and insect transmission studies will be necessary to determine the relationship of the new tomato virus to other whitefly-transmitted closteroviruses.

DUFFUS, J.E., H.Y. LIU, and G.C. WISLER. Lettuce chlorosis virus--A new whitefly-transmitted closterovirus in the southwest. Phytopathology (In press). 1994.

Lettuce infectious yellows virus (LIYV) has been a limiting factor in the production of crops in the desert regions of southwestern USA since 1981. Following the introduction of the B biotype of *Bemisia tabaci* into the region in 1990, the incidence of LIYV dropped significantly. A mixture of viruses including LIYV and a previously undescribed closterovirus herein termed lettuce chlorosis virus (LCV) have been isolated since 1991 from yellowed lettuce plants in the desert. LCV has long filamentous particles, and is transmitted by both the A and B biotypes of *Bemisia tabaci*. LCV can be distinguished from LIYV and other whitefly-transmitted closteroviruses by serology, dsRNA analysis, host range and insect-virus relationships.

DUFFUS, J.E. and E.G. RUPPEL. Diseases. Pg. 347-427 in The Sugar Beet Crop. D.A. Cooke and R.K. Scott, ed., Chapman and Hall. 1993. (Book Chapter)

Diseases have played an extremely important role in the current distribution of the beet sugar industry. The sugar-beet crop, a product of science, has largely depended for its success upon the ability of science to control destructive plant diseases.

The sugar-beet plants which were introduced from Europe to widely divergent areas of the world encountered numerous diseases unknown in their areas of development. Beet curly top virus virtually destroyed the sugar-beet industry in western USA in the 1920s and continued to be the principal factor limiting production in this region until the 1940s. In the absence of control measures (including resistant varieties and cultural methods) sugar beet could still only be grown in limited areas of western USA. Yellow wilt, first observed in Argentina in the 1920s, caused the complete collapse of the industry in that country and has severely limited the distribution of sugar-beet growing in Chile. Attempts to extend the cane sugar factory operations in the southern USA by using sugar-beet roots as an additional raw material failed completely because of the damage caused by two rots, *Rhizoctonia* crown rot and *Sclerotium* root rot. Rhizomania was first discovered in the mid-1950s on the Po river plains of Italy. By 1964 it had infested over 11,000 ha and caused their withdrawal from sugar-beet production. The disease was discovered in California in 1983 and has already been found in over 32,000 ha; it has caused some areas to go out of beet production and has seriously affected cropping in others.

This chapter reviews the literature of the major virus, fungal and bacterial diseases of sugarbeet.

DUFFUS, J.E. and D.C. STENGER. Squash leaf curl virus. C.M.I./A.A.B. Descriptions of Plant Viruses (In press). 1994.

Squash leaf curl virus (SLCV) is a virus with geminate particles, 22 X 38 nm. The circular single-stranded DNA genome is bipartite and consists of two similar-sized species. Known hosts are in the Cucurbitaceae, Leguminosae, Solanaceae, and Euphorbiaceae. The virus is transmitted by the whitefly, *Bemisia tabaci* and by inoculation with sap. The disease occurs in desert regions of the American Southwest and Mexico.

LEWELLEN, R.T. Case histories of early testing to identify sugarbeet lines with high performance. J. Sugar Beet Research 30:105. 1993.

Early testing is used to estimate the genetic potential of an individual or line at an early stage of development. The efficacy of early testing to identify improved lines of sugarbeet for general combining ability has been inconclusive. Monogerm line C762-17 was released in 1989 and lines C790-6, C790-15, and C790-54 were released in 1992. C762-17 was identified from pair-plant crosses between specific lines without recombination. Individual  $S_0$  plants within and among crosses were tested in 3-2ay hybrids. These tests identified plants that had better hybrid performance for sugar yield than their parental lines. Hybrids generated from  $S_0$  plants within paired crosses were more similar in performance than hybrids

among paired crosses. From population-790(C4) that had been improved by four cycles of  $S_1$  progeny recurrent selection, 100  $S_1$  progenies were evaluated in three locations for components of yield and disease resistance. Based on these tests, eight  $S_1$  progenies were selected and topcrossed. The  $S_1$  lines that became C790-6, C790-15, and C790-54 had significantly higher hybrid performance than the corresponding population hybrid. The performance of these monogerm lines strongly support the usefulness of early testing in a sugarbeet hybrid breeding program.

LEWELLEN, R.T. Sources, breeding, and performance of resistance to rhizomania in sugarbeet. J. Sugar Beet Research 30:106. 1993.

Rhizomania resistance breeding has been in progress at Salinas since 1984. A wide array of germplasm has been screened. Other than the factors from Holly (Rz) and Rizor, high levels of resistance are rare within sugarbeet. In contrast, resistance to rhizomania has been identified from many *Beta maritima* accessions. Eight of these sources of resistance have been enhanced by backcrossing into sugarbeet. Segregation within  $F_1$  and BC populations grown under rhizomania conditions usually suggest single dominant gene action. The allelic relationships of these different sources of resistance are not known. Tests of allelism between Rz and a factor from line PI 206407 (C28) suggested different genes. Field tests also suggested differences in performance. As the severity of disease increased, resistance from PI 206407 gave better protection than Rz. The combined resistance was better than either alone. In greenhouse and field tests, Rz and a factor from WB 42 (C48) reacted differently. In a field test under moderate and severe conditions, Rhizosen (Rz resistance) and Rizor had 30% reduction in yield, whereas a line with *B. maritima* sources of resistance (C50) had 6% additional loss. The effects of differences in gene frequencies and genetic backgrounds may have confounded these results and could not be discounted.

LEWELLEN, R.T. and E.D. WHITNEY. Registration of germplasm lines developed from composite crosses of sugarbeet x *Beta maritima*.

C48, C50, and C58 are sugarbeet germplasm lines developed by the USDA-ARS in cooperation with the Beet Sugar Development Foundation. These germplasm lines were derived from crosses between sugarbeet and *B. maritima* L.

C48 was released in 1988. It was developed from crosses of *B. maritima* lines WB41 and WB42 to C37 sugarbeet. Field tests showed that C48 is resistant to rhizomania. It has sugarbeet root and canopy type growth, is biennial, but in the absence of rhizomania has relatively low sugar concentration and yield.

C50 was released in 1988. It was developed from crosses of the Salinas collection of *B. maritima* accessions to Y54 sugarbeet. About 60 *B. maritima* accessions from Europe and the middle-East were successfully involved.

C50 is highly heterogeneous with 50% of the germplasm coming directly from *B. maritima*. It was released as a single population from which to search for desirable traits from *B. maritima* without the problems of growing many accessions with varying idiotypes and bolting tendencies. In an ongoing breeding program, it has been shown that C50 can be successfully used as a source of resistance to rhizomania and virus yellows.

C58 was released in 1989 as a source of disease resistance. It was developed from a composite of crosses made between C91 sugarbeet and *B. maritima* lines WB41, WB42, and WB151 from Denmark, WB187 and WB188 from England, WB318 from France, and WB169 from Italy. C58 is 50% *B. maritima*. It segregates for annualism, leaf and root color and shape, and disease resistance. In a series of greenhouse tests, 62% of the plants were highly resistant to rhizomania.

LIU, H.Y., J.E. DUFFUS and G.C. WISLER. Possible association of two soil-borne viruses with vascular necrosis of sugarbeet. Phytopathology 83:1421. 1993.

Two soil-borne viruses have been isolated recently from sugarbeet roots with vascular necrosis in the Imperial Valley of California. The infectious agents are mechanically transmissible. One of these viruses is isometric and approximately 25 nm in diameter. It contains a single species of single-stranded RNA of approximately 3.70 kb and a single capsid protein of approximately 31.0 kDa. Purified virus was infective and had an  $A_{260}/A_{280}$  ratio of 1.66. An antiserum to the purified virus had a titer of 1/512 in immunodiffusion tests. The particle morphology, protein coat subunits, and nucleic acid size are similar to those of tobacco necrosis virus (TNV). However, no serological relationship to TNV has been demonstrated in immunodiffusion and western blot analyses. Another spherical virus isolated from necrotic sugarbeet roots was serologically related to tomato bushy stunt virus. The distribution, economic importance, and the relationship of these viruses to the increasing vascular necrosis syndrome in the Imperial Valley is not known.

PILGERAM, A.L. and J.E. DUFFUS. Molecular analyses of *Polymyxa betae* and *Polymyxa graminis*. Phytopathology 83:1370. 1993

*Polymyxa betae*, the vector of beet necrotic yellow vein virus and beet soilborne virus, is an intracellular root parasite of plants within the Chenopodiaceae, Amaranthaceae, and Portulacaceae families. *Polymyxa graminis* is parasitic on

the roots of several grasses and vectors several devastating viruses (soilborne wheat mosaic virus, barley yellow mosaic virus, peanut clump virus, etc.). Although the host ranges of the two species are distinctive, morphologically they are quite similar. Ribosomal internal transcribed spacer sequences (ITS) from *Polymyxa*-infected root tissues have been amplified, and the products evaluated using restriction and RAPD analyses. ITS products from the two species, from *P. betae* isolates from different host plants, and from viruliferous and aviruliferous isolates of *P. betae* are compared.

WISLER, G.C., H.Y. LIU, and J.E. DUFFUS. Serological comparisons of beet necrotic yellow vein virus (BNYVV) with other rod shaped viruses of sugarbeet. Phytopathology 83:1421. 1993.

Five BNYVV isolates (three from California, one from Nebraska, and one from Idaho) and eight other rod-shaped viruses isolated from sugarbeet (two from Texas, five from Nebraska, and one from Idaho) were compared in western blot analyses. Those antisera which reacted only to BNYVV were to; (1) the C-terminus of the BNYVV capsid protein (CP), (2) the 14-kDa and 75-kDa nonstructural proteins (courtesy K. Richards) and, (3) four monoclonal antibodies to the CP of BNYVV (courtesy G. Grassi and L. Torrance). An antiserum to the 25-kDa nonstructural protein (K. Richards) reacted with four of the BNYVV isolates, but not with one which had been maintained by mechanical transmission for several years. An antiserum to the whole virion of BNYVV reacted strongly with homologous BNYVV isolates (MW of c. 22-kDa), but weakly with the eight other rod-shaped viruses of sugarbeet, with a MW of c. 24-kDa. In reciprocal tests, antisera to the two viruses from Texas reacted strongly with all eight rod-shaped isolates (c. 24-kDa), but weakly with the five BNYVV isolates (c. 22-kDa). An antiserum to the 42-kDa nonstructural protein (K. Richards) reacted with all BNYVV isolates (MW c. 42-kDa) and the eight other rod-shaped virus isolates (MW c. 43-kDa). All BNYVV isolates produced characteristic chlorotic local lesions on *Chenopodium quinoa*. Thus, BNYVV appears to be distinct from the other rod-shaped viruses of sugarbeet tested, based on the MW of the CP and reactivity with antisera to the 14-, 25-, and 75-kDa proteins.

YU, M.H. Biological Nematode Control in Sugarbeet Production. 7th Intl. Congr. Soc. Adv. Breed. Res. Asia & Oceania. Abstr. p. 174. 1993.

Cyst nematode and root-knot nematode are important plant pathogens of sugarbeet and are difficult to control. Plant parasitic nematodes spend at least part of their lives in soil; therefore, their activities and populations are influenced by both physical and biological factors in the soil. Control of sugarbeet nematodes is thus predicated on the population

density, activation timing, biological limitation, chemical application, and host plants. Multi-year crop rotation has been used extensively to control the cyst nematode. Several trap crops, such as oil radish, yellow mustard, or resistant sugarbeet lines, can be used for intermediate cropping. Nematode parasitic bacteria, fungi and other microorganisms are being investigated. Genetic sources of resistance to cyst nematode and root-knot nematode have been identified from *Patellares* wild beets and sea beet. Breeding sugarbeet resistant to nematode would be the most economical and environmentally sound tactic for the control.

YU, M.H. Growth and Reproduction Performance of Ovule-Induced Sugarbeet Plants. Sabrao Journal. pp. 24(1):47-55. 1992.

Plants derived from ovule cultures of eight sugarbeet (*Beta vulgaris* L.) breeding lines were studied for growth, seed set, and progeny ploidy. Leaf characteristics of the majority of the ovule-derived plants differed from the donor plants in vigor, size, shape, and texture. Stomatal guard cells of 52% of the ovule-derived plants contained 6.6-9.9 compared to 12-16 chloroplasts for diploids. Monoploid and diploid sugarbeets shared a 10-11.9 chloroplast range. Sixty percent of the plants were found to have 2n root tip chromosomes. Over 73% of ovule-derived plants pollinated with diploids set seed. Seed quantity ranged from only a few to an almost normal amount: 48% had 50 seeds or less per plant. Most of the progeny plants were vigorous and normal in appearance, and had 18 chromosomes. The results indicated that the majority of ovule-derived plants were monoploids, yet their outcrossed progeny were diploids.

YU, M.H. Identification of root-knot nematode resistance for sugarbeet breeding. 17th Intl. Congress of Genet. Volume fo Abstr. p. 118. 1993.

*Beta vulgaris* L. is one of the top two sucrose producing plants and a favored host of nematodes. *Meloidogyne* spp. cause root gall symptoms which severely limit sugarbeet yields and quality. Control of nematode in sugarbeet fields is challenging due to the nematode's wide host range and the increasing stringent restrictions on nematicide application. Identification of resistance to root-knot nematode and incorporation of resistance to sugarbeet, thus, becomes important. Screening >300 *Beta* germplasms, a *B. maritima* L. accession that segregated plants free from root gall formation and *M. incognita* reproduction has been identified. This is the first root-knot nematode resistance for sugarbeet breeding.

## DEVELOPMENT OF SUGARBEET BREEDING LINES AND GERMPLASM

R. T. LEWELLEN

BREEDING LINES C76-43 and C76-89 - These multigerm, open-pollinated breeding lines were released in 1993. They should combine resistance to rhizomania (Rz) with good tolerance to virus yellows. Pair crosses were made between plants from C31-43 or C31-89 and R76, a near-isoline of C31/6 with resistance to rhizomania. Full sib seed that was known to segregate for Rz was progeny tested under bolting induction conditions and evaluated for yield and sucrose. Based upon nonbolting tendency, % sucrose, and yield, stecklings of eight pair crosses involving C31-43 and six pair crosses of C31-89 were selected, combined within lines and increased. C76-43 and C76-89 will be evaluated in 1994 tests. Similar material and their hybrids were evaluated in 1993 as R276, R276Y, R276-43, R276-89, and R282 (combined R276-43, R276-89). Results of the performance of these lines and hybrids are presented in this report.

BREEDING LINE C918 - The population C918 was released in 1993. C918 is a self-fertile, multigerm, genetic male-sterile facilitated, random mated population that segregates for resistance to rhizomania (Rz). It also should have moderate tolerance or resistance to virus yellows, curly top, powdery mildew, Erwinia, and bolting. C918 and similar populations (popns-909, -911, -913, -915) were developed so that selfed families could be used for progeny evaluations yet be easily recombined. C918 will have traits similar to C37 or C46, its principal germplasm base. The development of C918 is given in the release notice. It will have a high frequency of self-fertility ( $S^f$ ) as it was developed from selected  $S_1$  progeny lines that had been selfed at Salinas under paper bags in the greenhouse. ( $S^S S^S$  genotypes will not produce seed at Salinas). The performance of populations similar to C918 (2913, 2915) and their hybrids is given in this report.

BREEDING LINES C909-34, C909-37, C911-4, C911-12, C911-14, and C911-50 - These lines were released in 1993. See release statement for greater details. As popn-918 (C918) was being developed, C37 and then C46 type lines were used as recurrent parents. As backcrossing and population improvement proceeded, populations-906, -907, -908, -909, -910, -911, -912, -913, and -915 were produced. Within population breeding and selection was done within these sources, including progeny ( $S_1$ , FS, HS) evaluations. C909-34 and C909-37 were extracted from popn-909 by  $S_1$  progeny evaluation. C911-4, C911-12, C911-14, and C911-50 were extracted from population-911. These lines segregate for resistance to rhizomania (Rz) and generally to Erwinia root rot and other diseases important in California. Results of the evaluation of these lines has been given in previous reports as well as in this one.

BREEDING LINE C890 - C890 was released in 1993 as a population that segregated for resistance to rhizomania (Rz). Subsequently there was

evidence that this may not be so. C890 is a monogerm (segregates for monogerm), O-type, self-fertile ( $S^f$ ), genetic male-sterile facilitated, random-mated population that is similar to C790. It was developed by backcrossing a source of rhizomania resistance to C790mmaa. At the time of its release, it was thought that it could be used as a source for producing monogerm, O-type, rhizomania resistant progeny families for population and line improvement. Earlier versions of C890 have been tested as lines 1890, 2890, and 2891. Progeny families from 2891 were evaluated and results are presented in this report.

BOLTING EVALUATION - The winter/spring/summer of 1992-93 at Salinas appeared to provide good bolting induction conditions. These results need to be viewed with caution, however. Bolting is under the influence of many factors, e.g., vigor of plant, nitrogen status, shading and other micro-climatic effects from intra- and inter-plot competition, plant populations, disease incidence and severity. That is, anything that influences growth rate appears also to influence bolting tendency. One factor that is very difficult to control is environment of the seed development. It is well known that seed developed under cool conditions (e.g., Spence field at Salinas) will express higher bolting than seed produced under warm conditions (e.g., the greenhouse isolation chambers at Salinas). Line vs. the apparent bolting tendency in hybrids can also be misleading, in part due to vigor and growth rate of the hybrid compared to a weaker line. Thus, although these appear to be good bolting tests, caution is needed and data and experience over years, locations, seed lots, etc. are needed to make definitive judgements about bolting tendency. Nonetheless, the rates of bolting in these tests suggest that selection for non-bolting tendency should be effective. A number of both multigerm and monogerm lines and populations were selected for nonbolting tendency in 1993-94.

SOURCES OF RESISTANCE TO RHIZOMANIA - Eleven sources of resistance to rhizomania have been backcrossed into C37 germplasm. All of these are targetted for release in 1994. In most cases it is yet undetermined what the allelic relationship is among these sources. Some are likely to have the same factor(s) for resistance. Sources of resistance include Rz (Holly), PI206407 (chard, C28), R22 (B.maritima, C50), WB42 (C48), WB41 (B.m. from Denmark), R04 (weed beet from Italy), R05 (obsolete Italian sugarbeet), Rima, WB151 (B.m. from Denmark), WB169 (B.m. from Italy collected by Coons), WB258 (B.m. from Italy collected by DeBiaggi in 1979). Results of some of this program are presented in this report. The breeding line numbers used to identify some of this material include R222R4 (R22), R232 (R04), R228 (PI07), R279 (Rz), 90-WIV (WB151), and R207/R208 (R05).

PERFORMANCE OF R22 SYNTHETICS - R22 population (released in unselected version as C50) is about 50% sugarbeet (line C54) and 50% a composite of Beta martima germplasm. From the unselected  $F_3$  synthetic R722, selections have been made for both resistance to virus yellows (see Tests 693, 893, 1393) and resistance to rhizomania (see Tests 693, B293, R793, R593, 2793, 2893, 2393, 2493). These selections were made to help assess

the genetic variability within B.maritima for disease resistance and factors for productivity. Results from the virus yellows selection program suggest that partial resistance to yellows occurs within B.maritima. Even more striking, there is evidence for high resistance to rhizomania. Because these resistance selections were partially based upon root and sugar yield (for virus yellows resistance), there is also evidence that factors for increased productivity may occur in B.maritima. The performance of R22 synthetics is given throughout this report and in the following tables.

SUGAR YIELD (lbs/a) UNDER SEVERE RHIZOMANIA,

RESISTANCE TO CYST NEMATODE - Cyst nematode resistant line C603 was derived from a cross with B883 from the Netherlands. In field tests at Salinas, it appeared to be resistant to the prevalent populations of Heterodera schachtii. In 1992, seed of C603, B883, B.procumbens, US H11, and others was furnished Dr. Lawrence Miller at VPI and State University. The purpose of these tests was to determine if isolates of H. schachtii from other locations could reproduce on C603. The results of these tests are presented below in the table.

#### REPRODUCTION OF ISOLATES OF BCN

<u>Variety</u>	<u>Isolates of H. schachtii</u>					
	<u>C1</u>	<u>C2</u>	<u>N1</u>	<u>M1</u>	<u>F1</u>	<u>F2</u>
US H11	+	+	+	+	+	+
B.procumbens	-	-	-	-	-	-
B883	-	-	-	-	-	-
C603	-	-	-	-	-	-

Data from L.Miller, VPI, 1994. Variation in development of five isolates of Heterodera schachtii on six sugarbeet x Beta procumbens interspecific hybrids. J.Nematology 26 (In press); and L. Miller. 1994. Development of four isolates and two intraspecific hybrids of Heterodera schachtii on three sugarbeet x Beta procumbens interspecific hybrids. Phytopathology 84 (In press).

C1 from tomato (CA); C2 from sugarbeet (CA);  
N1 from cabbage (NY); M1 from sugarbeet (MI);  
F1 & F2 from cabbage (Florida)

Subsequent to these studies, Dr. Miller identified an isolate called LSOG that in preliminary tests reproduced well on B.procumbens.

PERFORMANCE OF CYST NEMATODE RESISTANT HYBRIDS - Nematode resistant lines, populations, and hybrids were included throughout the testing program in 1993 (see results in this report). These materials are usually identified with an "N" prefix. Emphasis in the nematode resistance program is to combine resistance with rhizomania and other needs in germplasm with adaptation to the Western USA. The one constant with nematode resistant material is the very low sugar concentration. There is preliminary evidence however that under dual rhizomania/cyst nematode infested conditions, a hybrid with dual resistance is protected against both. Hybrid N203H15 which combines nematode resistance from C603 with rhizomania resistance from popn-915 under performed other hybrids in the absence of both diseases but out performed rhizomania resistant hybrids when tested under both conditions. These preliminary results are presented in the following table.

# PERFORMANCE OF NEMATODE RESISTANT HYBRIDS

Starting with B883 as the source of nematode resistance, BC<sub>4</sub> lines will be produced in 1994. These backcross populations theoretically will be about 97% curly top resistant germplasm and will have rhizomania resistance. From these, a selfing program will be initiated to fix resistance to cyst nematode, rhizomania, and other desired traits. Hopefully within these, lines can be identified that will approach commercial usefulness.

RESISTANCE TO ERWINIA and POWDERY MILDEW - The tests to evaluate reactions to Erwinia root rot (ERR) appeared to be good in 1993. A mixture of isolates was used to inoculate the tests. However, tests by Dr. A. Pilgeram suggested that the 1991 isolate from Imperial Valley was the most prevalent one to cause soft rot in the field. With the high emphasis on

rhizomania resistance and the conversion of breeding lines to resistance to rhizomania, there appears to have been a general erosion in resistance to Erwinia, powdery mildew, and bolting, as well as curly top, virus yellows, sucrose percentage, etc. within the base lines. Renewed efforts and emphasis are being made in 1994 to upgrade the combined resistance and performance of the Salinas germplasm base. The following Table summarizes briefly and demonstrates the loss of combined resistance in the rhizomania resistant germplasm.

COMPARISON OF DISEASE REACTIONS  
BETWEEN NEAR-ISOLINES

<u>Near- Isoline</u>	<u>Erwinia DI<sup>1</sup></u>	<u>PM Score<sup>1</sup></u>	<u>Bolting %<sup>2</sup></u>

<sup>2</sup>Test 493: Planted 11/12/92. Counted 7/8/93.

VIRUS YELLOWS RESISTANCE - Breeding for resistance to virus yellows (BYV/BWYV) has been an ongoing program at Salinas since 1955. Even though progress has been very slow, particularly for resistance to BYV, it is evident that compared to nonselected materials, tolerance to virus yellows has been achieved in this program. This is evident in the virus yellows tests and is demonstrated in the Table below. The breeding lines developed in the virus yellows program have been used as the base for the rhizomania resistance program. As shown above, there has been a general loss of combined disease resistance during this program. However, it appears that it has been possible to combine rhizomania resistance with the existing levels of virus yellows tolerance.

Notes: Test was grown in an area without rhizomania. BWV infection was evident by June, but BYV infection remained low. Powdery mildew developed late, after the effects of Bayleton ceased. PM was scored 9/14 & 9/27/93. Erwinia spread from nearby inoculated trials and accounted for the root rot.

<sup>1</sup>Y854 = C54. R080 is near-isogenic Rz\_line of C54. R722 = F<sub>3</sub> (sugarbeet x B.maritima) source population. R3 and R4 are third and fourth cycle synthetics selected for resistance to rhizomania among 4 month old roots where selection was based upon root type and freedom from rhizomania symptoms. Y and Y2 are first and second cycle synthetics selected for resistance to virus yellows (BYV/BWV) where 7 month old infected plants were selected on the basis of root size, shape, and % sucrose. R221 is C37 type with rhizomania resistance from WB41 and WB42.

Note: Test was grown in a field plot area free of rhizomania and cyst nematode. Virus yellows was mild and mostly BWV. Powdery mildew was controlled until late summer with Bayleton. Aphids were controlled with Metasystox-R and Lorsban. Root rot was counted at harvest and due to spread of Erwinia.

Note: Tests 693-1293 were grown under nondiseased or controlled conditions. There was no evidence of rhizomania.

Virus yellows and other diseases were mild. Root rot primarily due to Erwinia.

<sup>1</sup>Powdery mildew scored 9/14 & 9/21/93 on a scale of 0 to 9 where 9 = 90-100% of mature leaf area covered with mildew. Earlier in season, PM had been very well controlled with Bayleton.

<sup>2</sup>See Test 1493. R204 = rhizomania resistant selection within an accession from Italy with weed beet traits.

R232 = F<sub>2</sub>(C37 x R04).

<sup>1</sup>F82-546H3 = C562CMS x C546. 87-309H3 = C562CMS x C309. 1864 & 1867R are S<sup>f</sup>, A:aa, R<sub>2</sub> populations.

0864-#'s are progeny families selected from popn-864 on the basis of per se performance for components of yield and resistance to rhizomania. R080 = MM, R<sub>2</sub> line. R080-#'s are progeny families selected from line R80 on the basis of per se performance under virus yellows, rhizomania, and bolting conditions. R076, R078, and R176-43, -89 are MM, R<sub>2</sub> lines. R176-43 & -89 are similar to C76-43 & C76-89 combined. 1913/1915 is a S<sup>f</sup>, MM, R<sub>2</sub> population. Increase of 1911-4 was released as C911-4. R122R3 is 50% Beta maritima population. N103/N103-1 = C603/C603-1.

<sup>2</sup>Powdery mildew scored on 9/15/93 and 9/21/93. Test was treated with Bayleton for PM control. Development of PM was late and had minimal effect on yield.

Note: Agronomically test was very good. BWVY occurred. Some plants were infected with Erwinia.

Nitrogen status was high at time of harvest. Rhizomania or cyst nematodes were not detected.

Test was grown in a field plot area that had not been in sugarbeets for more than 20 years. There was no evidence of rhizomania or cyst nematode. Some Erwinia root rot occurred, having spread from Erwinia inoculated tests. BWV was evident in early June. Bayleton was used to control powdery mildew, and powdery mildew did not develop until September. 60 to 70 ton yields were common in this and adjacent USDA tests. At harvest, beets were still growing rapidly and needed 4-6 weeks more to use available nitrogen and fully exploit growing season, so that respective yields could be achieved.

<sup>1</sup>790-68H26 = C309CMS x C790-68. 309H3 = C562CMS x C309. R176-43,-89 is unselected version of C76-43,-89. 1915 is similar to C918. R076, R078, and R080 are near-isogenic Rz\_ lines of C31/6, C46/2, and C54.

<sup>2</sup>Powdery mildew was scored on a scale of 0 to 9, where 9 = severe infection. Scores were taken on 9/9/93 and 9/15/93.

<sup>1</sup>Evaluation of progeny families from MM, S<sup>f</sup>, A:aa, Rz populations 909, 911, 913, and 915. Progenies were previously tested per se and in testcross hybrids under nondiseased and diseased (rhizomania, BYV/BWV, bolting, Erwinia, powdery mildew, etc.) conditions and selected on the basis of these tests. Increases of lines 8909-34, 8909-37, 1911-4, 1911-12, 1911-14, and 1911-50 were released in 1993 as C909-34, C909-37, C911-4, C911-12, C911-14, and C911-50.

<sup>2</sup>Topcross hybrids of selected progeny families where 1865 tester is a mm, S<sup>f</sup>, A:aa, Rz population similar to C310. 2915H65 and 2865H13/2865H15 would be reciprocal population hybrids. See test 1793 for the same entries under BYV/BWV inoculated conditions.

<sup>1</sup>Test was uniformly inoculated with beet yellows virus (BYV) and beet western yellows virus (BWV).

TEST 1493. VIRUS YELLOWS EVALUATION OF MULTIGERM GERmplasm, SALINAS, CA., 1993

(cont.)

Variety <sup>5</sup>	Description	Acre Yield		Beets	Sucrose		Bolting	Rot	Beets/100'		Powdery Mildew <sup>3</sup>		Virus Yellow <sup>4</sup>	
		Relative <sup>2</sup>	%	Tons	%	%	%	%	No.	Mean	Mean	%	Mean	Mean
		Lbs												

Set 1 (1493-1) MM,O.P. Lines (cont.)

<sup>2</sup>Relative gross sugar yield between entries in BYV/BWV inoculated test 1493 and corresponding noninoculated entries in test 893. These tests were planted and harvested at different times. Individual ranking within tests is subject to experimental error. Thus, in addition to the effects of virus yellows, there would be differences due to cultural practices and random error. In a broad sense, relative gross sugar yield should give a fair estimate of the differences in resistance/tolerance to virus yellows. As with all field data, estimates of response to virus yellows infection will be improved by comparisons across tests and over years. Relative yield = 100(inoculated mean/noninoculated mean).

<sup>3</sup>powdery mildew scored from 0 to 9 where 9 = 90-100% of mature leaf area covered by mildew.

<sup>4</sup>virus yellows scored from 0 to 9 where 9 = 90-100% of the mature leaf area yellow.

<sup>5</sup>268 = Increase of obsolete O.P. variety US75 grown in the 1950's. C37 = YR (yellows resistant), ER (Erwinia resistant) selection from US75. R279Y = C37Rz. R228 = C37 with rhizomania resistance from PI206407. P201 & P202 = C37 x (SB x WB97, WB242). R278 = C46/2Rz. US H11 = (C562CMS x C546) x C36.

TEST 1493. VIRUS YELLOWS EVALUATION OF MULTIGERM GERmplasm, SALINAS, CA., 1993

48 entries x 6 replications, RCB; 1-row plots, 20 ft. long. ANOVA to compare means across sets.

<sup>1</sup>Test was uniformly inoculated with BYV/BWV.

<sup>2</sup>Relative gross sugar yield between entries in BYV/BWV inoculated test 1593 and corresponding entries in Tests 993, 1193, & 1293: Test 1593-1 corresponds to Test 1293; Test 1593-2 corresponds to Test 1193; Test 1593-3 corresponds to Test 993-1. (See footnote 2 for Test 1493).

<sup>3</sup>Powdery mildew scored from 0 to 9 where 9 = 90-100% of mature leaf area covered by mildew.

<sup>4</sup>Virus yellows scored from 0 to 9 where 9 = 90-100% of the mature leaf area yellow.

<sup>5</sup>790-68H26 = C309CMS x C790-68. 309H3 = C562CMS x C309. R076, R078 & R080 are near-isogenic Rz lines of C31/6, C46/2, & C54. R176-43,-89 is unselected version of C76-43,-89. N103, N103-1 are nematode resistant C306, C306-1. 1913, 1915 is similar to C918.

TEST 1693. VIRUS YELLOWS EVALUATION OF SELECTED PROGENIES, SALINAS, CA., 1993

Notes: Test was uniformly inoculated with virus yellows (BYV/BWV) on May 6, 1993. Yellows were uniform and severe. Powdery mildew was scored 9/15/93 after the efficacy of Bayleton ceased. Yellows symptoms (9 = severe yellowing) were scored 8/25 and 9/03/93. See test 993 for the same entries under non-virus yellows inoculated conditions.

<sup>1</sup>1865,1865-# tester is a monogerm population similar to C309/C310, but segregates for resistance to rhizomania. 1913,1915 is a multigerm, self-fertile, A:aa population that segregates for resistance to rhizomania. The progeny lines are extractions from popns-911,-913,-915. R176-43; -89 is unselected version of C76-43; -89. 1911-4, -12, -14, -50 are unselected versions of C911-4, C911-12, C911-14, & C911-50.  
<sup>2</sup>Relative gross sugar yield between entries in BYV/BWV inoculated Test 1793 and corresponding noninoculated entries in Test 993. See footnote 2 of Test 1493.

Notes: See Test 693 for performance under nondiseased conditions and Tests 2793-2 & R593 for performance under rhizomania conditions. Data from these tests suggested that rhizomania resistance selection and virus yellows resistance selection were particular for factors for resistance to rhizomania and virus yellows, respectively.

<sup>1</sup>See footnote 1 for Test 693.

VARIETY TRIALS, BRAWLEY, CALIFORNIA, 1992-93  
USDA-ARS. Irrigated Desert Research Station

Tests were located on 104 beds (3 acres) on south side of block J. Rotation previously had not included sugarbeet. All fertilizer was applied pre-plant as 46:0:0 and 11:52:0 for a total of 142 units of N and 125 units of P<sub>2</sub>O<sub>5</sub>. Rhizomania test B293 was located on 20 beds in block K. For many years a 3-year rotation included sugarbeet trials. Rhizomania was recognized in trials in 1989-90. Beets were not grown in 1990-91, but rhizomania trials were grown in 1991-92 and 1992-93. Rhizomania was severe in 1992-93. For block K, 129 units of N and 149 units of P<sub>2</sub>O<sub>5</sub> were applied preplant.

Summary: Arrangement of 1992-93 Tests

Test No.	Entries per Test	No. Reps	Rows per Plot	Plot Length	Harv Date	Test Design	Sugar Samples/Plot
B193 <sup>1</sup>	4	6	1	14 ft	5/20	1	1
B293 <sup>2</sup>	12	6	1	14	2	2	2
B393 <sup>3</sup>	16	4	1	10	3	3	3
B493	32	8	1	24	5/14	RCB	1
B593	32	8	1	24	5/17	RCB	2
B693	16	8	1	24	5/18	RCB	1
B793	8	8	1	24	5/18	RCB	1
B893	48	8	1	15	5/19	RCB	1
B993	24	8	1	15	5/20	RCB	1

Planted September 24, 1992. Watered 9/28/92 by sprinkler. After emergence, watered by furrow on 10/20/92, 11/13, 2/21, 3/9/93, 3/31, 4/21, & 5/4. Thinned 11/2/92. Poast (0.50 pt/A) for grass control. Thiocarb (2 pts/A) and Lorsban (0.75 pts/A) for flea beetle control.

<sup>1</sup>Variety x Date of Planting Effects of Whitefly infestation: Split-plot design with planting (watering) dates of 9/11, 9/28, 10/9 and 10/23/92.

<sup>2</sup>Effects of Variety x Harvest Dates on Rhizomania: Split-plot design with harvest dates on 4/16/93, 5/12/93, and 7/1/93.

<sup>3</sup>Root Rot Test: Split-plot design with 3 disease treatments. Inoculated with Phytophthora, Pythium aphanidermatum and noninoc. control. Not harvested for yield. Scored for root rot 7/1/93. Root rot did not occur. (Test in cooperation with Dr. J. Gerik, Holly Sugar).

Remarks - Nitrogen status was moderately high. Tests were off water only 3 weeks at harvest, so still lush. Powdery mildew not controlled and moderate at harvest. Low incidence of Empoasca but high infestation of mites. No significant problems or incidence of other diseases or pests noted. Field was uniform and test results should be reliable.

Acknowledgements - Clifford Brown, IDRS, for managing these trials. Holly Sugar at Brawley for field plot harvesting equipment and running sugar samples.

Note: Strain B of whitefly does not vector LIYV but may cause direct feeding injury. Four dates of planting were used to monitor whitefly populations on sugarbeet and to see if planting date caused significant differences in whitefly populations. Whitefly data were inconclusive, but trial was kept to see if differences occurred for varieties x dates of planting. Trial was at south edge of Block J and appeared to have a very high N status.

TEST B293.<sup>1,2</sup> EVALUATION OF DATE OF HARVEST x VARIETY ON PERFORMANCE UNDER RHIZOMANIA  
BRAWLEY, CA., 1992-93  
(cont.)

<sup>1</sup>Harvest Date 2 (May 12) closely corresponds to the harvest date of Test B793. Except for effects of rhizomania, performance in tests B293 and B793 (without rhizomania) should be similar.

<sup>2</sup>Rhizomania infection was severe at top of field to moderate at bottom of field. Root symptoms were moderate with little bearding; most symptoms involved internal vascular discoloration and necrosis followed by root rot as soils warmed. R222R4 always showed the most vigorous growth. Cyst nematode were also prevalent in this test.

<sup>3</sup>Two sets of 6 varieties were maintained together. These two sets would be 3 harvest dates x 6 replications split-plots. However, treatment means can be compared across these sets.

<sup>4</sup>% rot was calculated from the difference between stand counts and harvest counts. Negative values reflect experimental error in making these counts and probably are primarily due to doubles counted as a single plant during stand counts.

Conclusion: (Also see Test B692, p.63, 1992 Sugarbeet Research Report.) Test B293 was grown in same field plot area as Test B692. Consequently, effects of rhizomania were more severe in 1993 than in 1992. The results suggest that rhizomania can be devastating in the Imperial Valley. Effects of severe infestation showed in the fall growth and resulted in lower yield in the early harvest period. As conditions warmed and the beets were placed under increasing stress, they ceased to grow and accumulate sugar. As the season progressed, more and more root rot occurred. By July, highly susceptible varieties like US H11 had completely died (rotted). Moderately susceptible varieties also showed reduced yields and high levels of root rot. Only R222R4 with germplasm derived from wild beet (Beta maritima) has near normal yields and resists high levels of root rot.

Footnote: R278H39 is USDA filler; R78 = Rz version of C46/2. Entry 13 had poor stands. Yield was adjusted for missing feet of row but because of extent of gaps, should be considered an estimate. Poast was applied post emergence. Thiodan and Lorsban were applied for flea beetle control. Powdery mildew was not controlled and incidence was moderate at harvest. Empoasca were light but a heavy infestation of mites occurred just prior to harvest. The test was off water for just three weeks prior to harvest and the beets were lush. Test appeared to be uniform and reliable.

TEST R793. RHIZOMANIA YIELD TEST OF HYBRIDS WITH RESISTANCE TO RHIZOMANIA  
(IIRB RHIZOMANIA TEST), SALINAS, CA., 1993

(cont.)

Variety	Description	Acre Yield		Sucrose	Bolters	Beets/ 100'	Powdery Mildew	CLS
		Sugar	Beets					
		Lbs	Tons	%	%	No.	Mean	Score

NOTES: Test R793 was planted in a field plot area with moderate to severe rhizomania about 8 kilometers from the location of tests 2293 and 2693. Unlike tests 2293 and 2693, the plots were hand harvested and weighed in the tare laboratory after being trimmed and washed.

Powdery mildew was not controlled in this test, but was not severe. Natural infection with Cercospora leaf spot (CLS) occurred late. Except for the most susceptible entries, CLS probably did not affect yield. Cyst nematodes were evident at harvest. The development of rhizomania symptoms was very good. This should be a good test of differentiate reaction and performance under rhizomania conditions.

In the USDA entries, a hybrid of R222R4 was grown rather than R222R4 per se. 2915, R078, R176-43,-89, R080, and 1867R are breeding lines under development at Salinas with the Rz (Holly) source of resistance.

Powdery mildew was scored on 10/06/93 on a scale of 0 to 9, where 9 is most severe. Cercospora leaf spot was scored on a scale of 0 to 9, where 9 would represent 90-100% defoliation of mature leaves.

To convert pounds sugar per acre to kg/ha, multiply by 1.12. For tons roots per acre to tonnes/h, multiply by 2.24. % S = pol. RJAP = raw juice apparent purity = (total soluble solids x 100)/%S. To convert beets/100 ft. to beets per acre, multiply by 233. To convert beets/100 ft. to beets per hectare, multiply by 575.

Test was grown under sprinkler irrigation. Irrigation frequency was regulated to promote severe rhizomania and prevent loss of highly diseased plants.

TEST 2293. NON-RHIZOMANIA YIELD TEST OF HYBRIDS WITH RESISTANCE TO RHIZOMANIA

TEST 2293. NON-RHIZOMANIA YIELD TEST OF HYBRIDS WITH RESISTANCE TO RHIZOMANIA  
(IIRB RHIZOMANIA TEST), SALINAS, CA., 1993

Variety	Description	Acre Yield		Sucrose %	Bolters %	Root		Beets/ 100'	Powdery	
		Sugar	Beets			Rot	Rot		Mildew	RJAP
		Lbs	Tons			%	%		Mean	%

NOTES: Test was planted in field plot area about 500 meters from rhizomania plot area (see test 2693). The plot area for this non-rhizomania test had not been in sugarbeet for more than 20 years and rhizomania and nematodes were not evident at harvest.

The root rot in this test was caused by Erwinia carotovora betavasculorum and spread from adjacent powdery mildew-Erwinia root rot tests. Although powdery mildew control was attempted by two applications of Bayleton, infection pressure was very high and mildew occurred from about August 1, on. Powdery mildew was scored on a scale of 0 to 9 where 9 = 90 to 100% of the mature leaf area covered by mildew. Ratings were made on August 25 and September 1. This test was also near the virus yellows inoculated trials and after August 1, gradually many plants became naturally infected with virus yellows (BYV/BWV). Earlier aphids were controlled with Metasystox-R and Lorsban.

In the IIRB set of entries, US H11 was added as a highly rhizomania susceptible check and C39R (R039C5) as a moderately resistant line with quantitative resistance. In the set of USDA entries, 6770 was used as a susceptible, high %S entry and "Rhizoguard" as a moderately resistant hybrid. R276Y, R280Y, R080, and R078 are breeding lines developed at Salinas with the R<sub>z</sub> (Holly) source of resistance. 88-790-68H26 is a susceptible F<sub>1</sub> CMS hybrid. R222R4 is the fourth cycle synthetic from a population that is 50% Beta maritima germplasm. R232 is an F<sub>2</sub> line between C37 sugarbeet and a rhizomania resistant, half-wild beet accession from Italy.

RJAP = raw juice apparent purity = (total soluble solids x 100)/%S. To convert beets/100 ft. to beets per acre, multiply by 233. To convert to beets per hectare, multiply by 575. To convert pounds/acre sugar yield to kg/h, multiply by 1.12. For tons roots/acre to tonnes/h, multiply by 2.24

See tests 2693 and R793 for results under rhizomania conditions.

TEST 2693. RHIZOMANIA YIELD TEST OF HYBRIDS WITH RESISTANCE TO RHIZOMANIA,  
(IIRB RHIZOMANIA TEST), SALINAS, CA., 1993

8 entries x 8 replications, RCB  
2 row plots, 20 ft. (6.1M) long, 71 cm wide

Planted: May 17, 1993  
Harvested: November 5, 1993

F value		18.5**	8.97**	79.8**	19.1**	5.8**	19.1**	12.7**

NOTES: US H11 is a highly rhizomania susceptible hybrid. R039C5 (=C39R) is a multigerm breeding line with quantitative resistance developed at Salinas. See test 2293-1 for same IIRB entries under non-rhizomania conditions. Also see test R793 for the IIRB entries tested under rhizomania conditions in a different location.

To convert pounds/acre sugar yield to kg/h, multiply by 1.12. For tons roots/acre to tonnes/h, multiply by 2.24. %S = pol. RJAP = raw juice apparent purity = (total soluble solids x 100)/%S. To convert beets/100 ft. to beets per acre, multiply by 233. To convert beets/100 ft. to beets per hectare, multiply by 575.

Powdery mildew was scored on 10/20 and 10/28, on a scale of 0 to 9, where 9 = 90-100% of the mature leaf area covered by mildew. Through most of the growing season, PM was controlled with Bayleton.

Variety <sup>1</sup>	Description	Acre Yield		Bolters	Beets/ 100'	Powdery Mildew	RJAP
		Sugar Lbs	Beets Tons	Sucrose %	No.	10/22	%

NOTES: Test was grown in Field C under moderate to severe rhizomania conditions. Powdery mildew was not controlled. Cyst nematodes were evident at harvest. Cercospora infection occurred late but caused little damage.

<sup>1</sup>R230 combines resistance from Rz and C28 (PI206407) in a C37 background. R228 = C28 backcrossed to C37. P201 = WB97 & 242 in a C37 background. R232 = Italian wild beet (weed beet) source crossed to C37. N244 = F<sub>3</sub>BC<sub>1</sub> nematode resistant line. N203H15 = F<sub>1</sub>BC<sub>1</sub> cyst nematode resistant hybrid between rhizomania resistant (Rz) popn-915 and C306, C603-1. R222R4 = 4th cycle selection synthetic from population that is 50% Beta maritima. 2916 = new composite population. Z230 = population that is 25% high sugar Polish germplasm.

<sup>2</sup>R039C5, C7, and C8 are synthetics from cycles 5, 7, and 8 for mass selection for resistance to rhizomania.  
Y439 = CO = unselected source. Resistance was based upon visual symptoms in 4 mon. old plants. R231-#'s and R276-#'s are selections from C31/6.

<sup>3</sup>R122R3 and R222R4 are synthetics from cycles 2 and 3 for mass selection for resistance to rhizomania from R722. R722 = F<sub>3</sub> popn between Y54 sugarbeet and B.maritima accessions. R280 & R280Y are near-isolines of Y54 (C54). R280-#'s are increases of half-sib lines selected from line R80.

<sup>4</sup>R279, R279Y, and R279R2 are near-isolines of C37. R230 (Rz & PI07), R228 (PI07), P201 (WB97), R232 (R04) are lines with rhizomania resistance in a C37 background. R278 and R278Y are near-isolines of C46/2. N244 segregates for resistance to rhizomania (Rz) and cyst nematode. 2914 is S<sup>1</sup> version of C39R. 90-WIV has rhizomania resistance from WB151. R222R4 see footnote 2.

<sup>8</sup>See Tests 793, 893 and 1493 for the performance of these lines under nondiseased and virus yellows conditions. See R593 and R693 for other rhizomania tests. See 493 for bolting evaluation and 2193 for Erwinia root rot evaluation.

<sup>5</sup>P202 is from a cross to WB242. R233 (Rz & PI07) and R229 (Rz) are backcross lines to 5747. 2911Y, 2913, 2913Y, 2915, 2915Y, & 2916 are MM,S<sub>I</sub>,A:aa populations with Rz. Z220 is 50% Polish %S germplasm. Z230 is 25% Polish %S germplasm. N203H15 is a hybrid with resistance to rhizomania and cyst nematode. R207 and R208 have rhizomania resistance from Rz and Italian gp.

<sup>6</sup>Powdery mildew scored 10/20/93 and 10/28/93 on a scale of 0 to 9 where 0 = no visible infection.

<sup>7</sup>Root rot due to Erwinia.

<sup>1</sup> 2J0181 & 2J5025 are rhizomania susceptible, cyst nematode resistant hybrids from Betaseed. N203H15 is resistant to both cyst nematode and rhizomania. N103, N103-1 = C603, C603-1 which are homozygous, cyst nematode resistant lines. N203H89 is rhizomania susceptible, cyst nematode resistant hybrid. N244 & N152 are populations that segregate for Rz and cyst nematode resistance.

Note: Test was grown under moderate to severe rhizomania conditions in a field plot area known to be infested with cyst nematode.

Notes: Test was in a field with severe rhizomania but in addition, other soil-borne problems apparently occurred. Following emergence, many seedlings appeared to be infected by Aphanomyces. Thinning was delayed and best plants were saved when thinned. However, an Aphanomyces like disorder continued to show in some areas of the field. Roots at harvest were often sprangled. Cyst nematodes were evident at harvest and may have reduced yields. Cyst nematode infestation may account for the better than expected performance of nematode resistant hybrid N203H15. The wide dispersion in yield is thought to be primarily caused by differential reaction to rhizomania, but many other factors appeared to significantly influence yield in this test also.

Foliar diseases and other viruses did not appear to be important in this test.

% sugar is higher than usual for rhizomania infected tests. Sugar concentration and appearance of plants at harvest suggested that a nitrogen deficiency occurred. A total of more than 240 units of nitrogen was applied preplant and in two sidedress applications. Frequent sprinkler irrigations (2x per week) to promote severe rhizomania and keep infected plants alive may have moved the nitrogen out of the root zone of the disease impaired plants growing in this sandy loam soil.

One entry gave very encouraging results. Despite all the soil-borne problems, for a five-month crop, R222R4 would appear to have a normal, nondiseased performance. This has been observed in other tests at Salinas and Imperial Valley for this line that was derived from composite crosses between sugarbeet and many *Beta maritima* accessions. It is yet unknown whether this is high resistance to rhizomania and/or resistance to rhizomania and other soil-borne disease (Aphanomyces, cyst nematodes, etc.).

Because of the complexity of root problems, it did not appear that scoring individual plants or plots for rhizomania symptoms would be meaningful. Gross sugar yield has appeared at Salinas to be the most useful criterion for evaluating a variety's reaction to rhizomania. Entries that are significantly higher yielding than the susceptible check (US H11) should be considered to have partial resistance or tolerance to rhizomania.

<sup>1</sup>US H11 is a susceptible check. This version, however, appeared to be more tolerant to rhizomania than previous versions. Rizor is a commercial hybrid with resistance to rhizomania used in Europe and Japan. N203H15 is a cyst nematode resistant hybrid between rhizomania resistant (Rz) population-915 and homozygous, nematode resistant lines C603 and C603-1. R222R4 is the 4th cycle selection for resistance to rhizomania from a population that is half Beta maritima. R232 is an F<sub>2</sub> line from a rhizomania resistant, partially wild beet accession from Italy crossed to C37 sugarbeet. R276Y is the Rz near-isogenic line of C31/6. R078 and R080 are the Rz near-isogenic lines of C46/2 and C54. 88-790-68H26 is a rhizomania susceptible, monogerm, F<sub>1</sub>CMS hybrid.

<sup>2</sup>Powdery mildew was scored twice on 10/20/93 and 10/28/93. Test was treated with 16 ounces a.i./acre of Bayleton on August 4, 1993 and remained free of mildew until late in September. Mildew probably had little affect on yield. Powdery mildew scored from 0 to 9 where 9 = 90-100% of mature leaf area covered with mildew. Powdery mildew reaction is thought to be influenced by severity of rhizomania; therefore, partially rhizomania resistant varieties may appear relatively more susceptible to powdery mildew than the rhizomania susceptible entries.

<sup>3</sup>WS: Entries submitted by Western Sugar Committee.

<sup>4</sup>JG-H: Entries submitted by Joint Grower-Holly Committee.

NOTES: Test was designed as a 64 entry x 8 replication test. Entries 1 thru 51 were for the coded rhizomania test. Entries 52 thru 57 were from a private seed company. Entries 58 thru 64 were entries and checks included by the USDA. Because of cultural and disease problems within replications 2,3, and 7, these were deleted from the ANOVA, and final results are presented as a five replication test.

A gradient in soil fertility and disease expression occurred from the top to the bottom (direction of replication) of the field. A more serious gradient also occurred from the left to the right side of the test. Rhizomania and other soil-borne problems were moderate to severe. In addition to rhizomania, what appeared to be Aphanomyces caused seedling loss, sprangling, and stunted growth. Cyst nematodes were observed at harvest. Other foliar and virus diseases did not appear to be significant.

<sup>1</sup>USDA entries and checks: US H11 accessed in April 1993; it appeared in this and other rhizomania tests to be different (more tolerant) than US H11 previously used. 6770 is a high % sugar, susceptible check used in most 1993 tests at Salinas. Rizor was obtained from SES in 1993. R076 and R080 are RZ near-isogenic lines of C31/6 and C54. R222R4H20 is a hybrid between a susceptible F<sub>1</sub>CMS hybrid and pollinator derived from a sugarbeet x Beta maritima population; it is 50% B.maritima.

<sup>2</sup>Powdery mildew was controlled until late September with 16 ounces a.i./acre Bayleton. It was scored on 10/18/93 and 10/28/93 on a scale of 0 to 9 where 9 is highly susceptible.

TEST 3193. RHIZOMANIA EVALUATION/SELECTION OF S<sub>1</sub> MONOGERM LINES, SALINAS, CA., 1993

112 entries x 2 replications  
1-row plots, 20 ft. long

<sup>1</sup>2859Am(Sp)-#'s, 2865Am(Sp)-#'s, 2867Am(Sp)-#'s, and 2891Am(Sp)-#'s are S<sub>1</sub> lines from their respective populations. The populations segregated for both Rz and monogerm. Unbagged, monogerm, fully fertile plants were tagged in field increases to produce S<sub>1</sub> seed. Some plants in these lines may be from outcrosses within the population and be half-sibs rather than S<sub>1</sub>'s.

<sup>2</sup>Visual rating of canopy where 1 = homozygous resistant (RzRz), 2 = segregation, 3 = homozygous susceptible.

<sup>3</sup>Vigor rating of canopy where 1 = vigorous to 5 = weak.

<sup>4</sup>Color rating of canopy where G = green, Y = yellowish, V = segregation or variable.

<sup>5</sup>Uniformity of canopy where 1 = highly uniform to 5 = highly variable.

\*PM Mean = Average of reading taken 07/02 & 08/03/93.

Up to 1200 feet of row per entry were grown for the purpose of evaluating and selecting for nonbolting tendency. Nonbolted mother roots reselected on the basis of % sugar were selected from lines R276Y, R276-43, R276-89, R276, R280, R280Y, R278, R278Y, 2915, 2865m, and F92-790-15. Seed will be produced in 1994.

Note: See test 3193, S<sub>1</sub> progeny test of monogerm lines for rhizomania resistance. Progeny lines of 2859Am were evaluated for nonbolting tendency (Test 393) and resistance to rhizomania (Test 3193). Stecklings from the best lines have been selected and will be topcrossed using genetic male sterile segregates to determine GCA. Popn-859 is nearly equal to C859.

Single plants of C790-6, C790-15, and C790-54 were selfed under bags in the greenhouse. The selfed progeny were planted for evaluation and selection for nonbolting tendency. Among line variability suggests genetic difference for bolting resistance. Based upon these data, a mother root and steckling nonbolting selection was made within C790-15. Seed will be produced in 1994.

TEST 2093. ERWINIA/POWDERY MILDEW EVALUATION OF HYBRIDS AND  
MONOGERM SELF-FERTILE LINES, SALINAS, CA., 1993

(cont.)

Variety	Description <sup>1</sup>	Stand		Harv.		Erwinia Reaction <sup>2</sup>		P.M. <sup>3</sup>	
		Count/ Plot	Count/ Plot	Count/ Plot	Count/ Plot	DI	% Resistant	DI	Avg.

Tests 2093 and 2193 appeared to be good tests to evaluate Erwinia root rot. Mixed inoculum of four isolates was used. The most virulent and aggressive one appeared to be the Imperial Valley isolate from 1991. Based upon the checks, these tests should be reliable for evaluating reaction to Erwinia.

<sup>1</sup>See Test 2193 for more detailed descriptions of components of hybrids and releases.

<sup>2</sup>Erwinia root rot: DI = average % rot per root at harvest; % resistant = percentage of roots scored 0 and 1% rotted.

<sup>3</sup>Powdery mildew not controlled. Scored on a scale of 0 to 9, where 9 = 90-100% of mature leaf area covered by visible mildew. Powdery mildew scored on 08/24, 09/02, & 09/16/93.

Note: *Erwinia* tests were inoculated with four isolates. Tests by Dr. Alice Pilgeram suggest that most infection was due to a 1991 isolate from the Imperial Valley. Based upon experience with *Erwinia* tests over the past 20 years, these are particularly good trials for evaluating differences.

LSD (.05)			1.5	1.3	1.5	1.3	1.4	1.4	1.0
C.V. (%)			10.6	115.3	61.6	34.7	25.3	20.6	26.5
F value			3.5**	2.0**	2.9**	5.4**	6.0**	6.0**	6.5**

Footnote: Powdery mildew scored on a scale of 0 to 9; where 9 = 90-100% of visible leaf area infected. Mean value (area under disease progress curve) most likely represents varietal reaction and differences among varieties. Scoring was stopped when most susceptible entries and US H11 started having lower values.

TEST 1993. INHERITANCE OF POWDERY MILDEW RESISTANCE, SALINAS, CA., 1993

\*Mean of 4 to 8 replications.

A high level of resistance to powdery mildew was identified in Beta maritima WB97 and WB242 by Dr. E.D. Whitney. Without prior selection, BC<sub>2</sub>F<sub>1</sub> testcrosses (87% sugarbeet) were made and evaluated for the occurrence of highly resistant plants and to get some information on the inheritance of resistance. Plants within individual testcross families appeared to segregate. From a few of these families, the most resistant plant were selected and will be entered into an inheritance study. Backcrosses will continue to be made to sugarbeet to transfer this resistance.

<sup>1</sup>Powdery mildew scored 8/30 and 9/16 on a plot basis on a scale of 0 to 9 where 9 = highly susceptible.

<sup>2</sup>Rating of % susceptible plants within a plot. A plant was considered resistant if it showed no powdery mildew until near leaf sevenscence (ratings of 0 and 1).

TEST RZM 393. 1993 EVALUATION OF AMES PI #'s FOR VIRUS YELLOWS AND RHIZOMANIA  
SALINAS, CA., 1993  
(cont.)

- 1 #1 End use based upon field plot appearance where: 1=chard; 2=DDR-like; 3=DDR, chard, spinach; 4=fodder; 5=sugar; 6=wild beet type; 7=mixed, 8=annual.
- 2 #5 Population Uniformity: 1=all plants alike; 2=uneven different types; 3=mixed, green, red, yellow, high, low, large leaves, small leaves, etc.
- 3 #12 Mature Leaf Blade Pigmentation: 1=light green (chard), 2=green, 3=red & green, 4=red, 5=mutant.
- 4 #19 Petiole Color: 1=green, 2=pink, 3=red, 4=candy stripe, 5=yellow, 6=mixed.
- 5 #37 Bolting Tendency without cold induction: 1=B-(annual)=100%, 2=bb(biennial)-0%, 3=B:bb(mixed) 1-99%. Readings 8/11 and 9/25/93.
- 6 #61 Beet Western Yellows (BWV): 0=immune; 1=very resistant; 3=resistant; 5=intermediate; 7=susceptible; 9=highly susceptible based upon yellowing of leaves. Readings 9/27 and 11/30/93.
- 7 #62 Cercospora was not severe enough to classify on 9/24/93. Remaining nonbolted plants were classified on 11/30/93 on a scale of 1-9 with 9 having symptoms on every leaf.
- 8 #66 Powdery Mildew classified on 10/6/93 on a scale of 0 to 9 where 9 = 100% of leaf area mildewed.
- 9 #74 Rhizomania: DI-disease index based upon 0=no visual symptoms; 1=very minor root symptoms; 3=normal tap root, slight bearding; 5=wine-glass shaped, bearded, moderate damage; 7=severely damaged, loss of tap root; 9=dead due to rhizomania %Healthy=classes (0+1+2+3)/total. Classified at time of harvest, 12/93.
- 10 RZM scored on annual plants only on a plot basis. Notes were taken on Annual plants 9/25/93. Plants were pulled and discarded at that time.
- 11 Harvest counts were made only on nonbolting plants when they were scored for DI and % Healthy RZM.

64 entries = 52 PI lines from Ames + 12 USDA checks. Checks are: US H11 = highly susceptible to rhizomania, mod. susceptible to BWV; R139C7 = C39R = moderately resistant to BWV and rhizomania; SP 7622-0 = susceptible to both BWV and rhizomania; R223 = composite of plants from B.maritima PI lines that showed resistance to rhizomania in 1991 test; R222R4 = cycle 4 synthetic of sugarbeet x B.maritima selected for resistance to rhizomania; R276-89 = sugarbeet line that segregates for Rz resistance to rhizomania.

Conclusion: Roots within some lines of B.maritima showed resistance to rhizomania. Two hundred individual plants were selected and will be crossed to sugarbeet to determine the nature and inheritance of this resistance. Many of the B.maritima lines showed very mild symptoms to BWV. The dark green, thick leaves of B.maritima have a tendency to mask virus yellows symptoms. Crosses to sugarbeet will be made to determine if this apparent resistance is heritable. Plots were found free of nematode infestation but this is thought to be field variability rather than genetic resistance.

CHARACTERIZATION OF THE VARIATION  
AMONG FUROVIRUSES INFECTING SUGARBEETS

G. C. Wisler, J. E. Duffus, and H.-Y. Liu

BNYVV was first detected in the U.S. in 1983 (Duffus et al., 1984). Several other viruses with similar particle morphology to BNYVV have been isolated from sugarbeet roots from Texas (Liu and Duffus, 1987), Nebraska, Idaho, and Colorado. Some of these isolates have been shown to cross-react with antisera to the BNYVV virion in ELISA tests and in western blot analyses. Thus, the possibility exists for misdiagnosis in sensitive tests which are based on serology of the capsid protein.

BNYVV isolates from Europe have been extensively studied with regard to the genomic organization, function of encoded proteins, and transmission by *Polymyxa graminis*. Many serological and nucleic probes have been developed to different regions of the BNYVV genome. In order to fully characterize and distinguish BNYVV from the other related furoviruses of sugarbeet, similar investigations must be done.

Serological analyses including enzyme-linked immunosorbent assay (ELISA), western blot, and immunodiffusion have been used to evaluate the BNYVV isolates from the U.S., as well as eight other furoviruses of sugarbeet. Serological probes, both polyclonal and monoclonal antisera, have been kindly supplied by several researchers (K. Richards, L. Torrance, and G. Grassi). These antisera have been produced to both structural (i.e., coat protein) and nonstructural (i.e., proteases, polymerases, movement protein) proteins of BNYVV and to two non-BNYVV furoviruses which originated from Texas. In addition, nucleic acid primers specific to the BNYVV genome were used in polymerase chain reaction (PCR) analyses. These techniques were used to evaluate the similarities and differences among the BNYVV isolates and between BNYVV and the other furoviruses of sugar beet. The ability of *P. betae* to transmit some of the non-BNYVV isolates was also evaluated.

The nature of relatedness between five beet necrotic yellow vein virus (BNYVV) isolates, (three from California, one each from Nebraska and Idaho) and eight other rigid, rod-shaped virus isolates of sugarbeet (two from Texas, five from Nebraska, and one from Idaho) was evaluated in this study using western blot analyses, immunodiffusion, and RT-PCR. Antisera to the BNYVV virion showed strong reactions in western blots at ca. 22-kDa for the five BNYVV isolates, and weak reactions at 24-kDa for the eight other rod-shaped virus isolates. Reciprocal tests using antisera to the whole virion of two rod-shaped virus isolates from Texas (referred to as beet soil-borne mosaic virus-1 and -2; BSBMV-1 and -2, Liu and Duffus, 1987) showed strong bands at 24-kDa for all eight rod-shaped isolates and weak bands at 22-kDa for the five BNYVV isolates. Antisera to the C-terminus of the BNYVV capsid protein, seven BNYVV monoclonal antibodies, and the

75-kDa and 14-kDa nonstructural proteins of BNYVV reacted only with the five BNYVV isolates. Antisera to the 25-kDa nonstructural protein reacted to three of five BNYVV isolates. Antisera to the 42-kDa nonstructural protein reacted with all five BNYVV isolates at ca. 42-kDa, and with the eight other isolates at ca. 44-kDa. Results of western blot analyses are summarized in Table 1.

No cross-reactivity between BNYVV isolates and those isolates related to BSBMV-1 and -2 was seen in reciprocal immunodiffusion tests using purified virus preparations (ca. 0.1 mg/ml) and crude sap as the antigen.

The products observed in RT-PCR among four BNYVV isolates (two from California, one each from Idaho and Nebraska) using primers specific for RNA 1, 2, and 3 were identical, whereas the products for RNA 4 varied. BSBMV-1 and -2 and a related isolate from Nebraska (NE10) did not react with any BNYVV primer pair tested. Results from RT-PCR tests are summarized in Table 2.

Preliminary transmission studies indicate BSBMV-2 and NE10 to be transmitted by *Polymyxa betae* Keskin. Results from this study suggest that the isolates related to BSBMV-1 and -2 belong to the furovirus group, but are distinct from BNYVV.

## Genetic Analysis of *Polymyxa betae* infected sugar beet roots using the polymerase chain reaction.

A.L. Pilgeram and J.E. Duffus. USDA-ARS, Sugarbeet Research Unit. Salinas, CA.

*Polymyxa betae*, the fungal vector of BNYVV, is an obligate root parasite of sugarbeet. Total DNA was isolated from healthy beet tissue and *Polymyxa*-infected root tissue and amplified using the polymerase chain reaction (PCR)(1,2). DNA was amplified using primers specific for fungal ribosomal DNA (ITS 2 and ITS 4) (3) and with several non-specific RAPD (random amplification of polymorphic DNA) primers (4). DNA polymorphisms within the fungal ITS (internal transcribed spacer) regions of the ribosomal DNA were not observed in different isolates of *P. betae* infecting sugarbeet (Fig.1). A single 750 bp (base pair) amplification product was amplified from non-infected sugarbeet tissue. An additional 480 bp product was present in amplifications from *Polymyxa* -infected sugarbeet roots. The relative intensities of the 750 bp and 480 bp bands were variable in different preparations and may represent differences in the proportion of fungal DNA within the total DNA preparation.

Fig.1. PCR analysis of the ribosomal ITS1 region of non-infected (USH11) and *Polymyxa*-infected *Beta vulgaris* (ATCC (American type culture collection), CA 1, CA 2, ID 1, ID 2, CO, MT, CA 2). Molecular weight standard was  $\lambda$  DNA digested with restriction enzymes *Hind*III and *Eco*RII

DNA from *Polymyxa*-infected *Portulaca* and *Polymyxa*-infected *Amaranthus* was also amplified using the ribosomal ITS primers (Fig.2). A single product (~750 bp) was amplified from DNA isolated from non-infected *Amaranthus* and no product was

amplified from non-infected *Portulaca*. An additional 620 bp or a 500 bp product were observed when DNA from different *Polymyxa*-infected *Amaranthus* were amplified. A slightly smaller product (~480 bp) was periodically amplified from infected-*Portulaca*.

Fig.2. PCR analysis of the ribosomal ITS1 region of *B.vulgaris* (USH11), *Polymyxa*-infected *B.vulgaris* (CA 2), *A.retroflexus* (Ar), *Polymyxa*-infected *A.retroflexus* (Ar 1, Ar 2), *P.oleraceae* (Po), and *Polymyxa*-infected *P.oleraceae* (Po 1). Molecular weight standard was λ DNA digested with restriction enzymes *Hind*III and *Eco*RI.

Total DNA from sugarbeet roots was also amplified using random DNA primers (RAPD analysis). Several products were present in amplifications of DNA from *Polymyxa*-infected root tissue that were absent from amplifications of DNA from non-infected tissue. In addition, there was some variation in RAPD products when DNA from different sugarbeet isolates of *P. betae* were amplified. Putative *P.betae*-specific RAPD products have been excised from agarose gels and cloned into pCR-Script plasmids (Stratagene). These RAPD clones will be used as probes in Southern hybridizations with DNA isolated from *Polymyxa*-infected beet tissue.

**Fig.3.** RAPD amplification of Total Root DNA using Operon primer (AB-02). *B.vulgaris* (USH11), *Polymyxa*-infected *B.vulgaris* (ID, CA 1, CA 2). Putative *P.betæ*-specific products are indicated. Molecular weight standard was λ DNA digested with restriction enzyme *Hind*III.

**Project Title:** Evaluation of Photosynthetic Parameters in the Selection of Varieties with Improved Rates of Sugar Production

**Project Number:** # 250

**Project Leader:** Norman Terry, Professor

**Other Personnel:** Adel M. Zayed                      Postdoctoral Researcher  
Jodi Azulai                                      Staff Research Associate

**Project Location:** 111, Koshland Hall, Dept. Plant Biology,  
University of California,  
Berkeley, CA 94720 Tel:(510) 642-3510

**Justification for Research:**

The overall goal of this research is to identify physiological parameters in young plants which can serve as markers to facilitate the selection of superior-yielding sugar beet genotypes. Specifically we have chosen chlorophyll fluorescence since our results show that the sucrose content of storage roots is linked physiologically to chlorophyll fluorescence. Large numbers of very young plants can be screened very quickly using the highly portable and sophisticated pulse modulated PAM fluorometer. The idea we wish to test is that pulse-modulated fluorescence can be used as an innovative screening method for the rapid identification of plants with superior yield potentials. In previous years, we found three fluorescence parameters,  $q_E$ ,  $(F_V)_S$  and  $F_V/F_m$ , which were highly promising as yield predictors, i.e., selection for these parameters in a population of young plants was successful in predicting which plants would later have high sucrose yields or % sucrose. The long-term goals of our research are 1) to develop the fluorescence approach into a simple and easily-workable technique for the rapid selection of high yielding genotypes, and, 2) to apply the technique for the actual development of new better-yielding varieties.

**Summary of Literature Review and Progress-to-Date:**

1. Literature Review

Chlorophyll fluorescence emitted by green plants is a measure of the photosynthetic activity of the leaf and originates mainly from chlorophyll a in photosystem II (PS II). Hence, fluorescence yield reflects the properties of excitation and energy conversion at PS II. However, due to the functional connection of PS II to the other components of the photosynthetic apparatus, fluorescence yield is considered to be an indicator of the whole complex process (Schreiber and Bilger, 1987). Recent improvements in fluorescence techniques, particularly the development of the pulse modulation chlorophyll fluorometer, have served to increase the value of fluorescence as a nonintrusive method of monitoring photosynthetic events and judging the

physiological state of the plant (Krause and Weis, 1991). Recent studies have proven that chlorophyll fluorescence provides a rapid non-destructive method for studying heat and drought stress tolerance in plants (Ogren, 1990; Prange et al., 1990; Jefferies, 1992; Smillie, 1992).

Apart from the research conducted in our own laboratory, there are very few if any studies which have attempted to correlate fluorescence parameters with root sucrose yield. It is thought that sucrose storage and partitioning is physiologically linked to photosynthetic rate (Wardlaw, 1990) and that changes in the latter are reflected by changes in fluorescence (see also Krause and Weis, 1991). Interestingly, Krause and Weis (1991) indicated that the  $F_v/F_m$  ratio has become an important and easily measurable parameter of the physiological state of the photosynthetic apparatus in intact plant leaves. Furthermore, Schreiber and Bilger (1987) stated that high levels of  $(F_v)_s$  are associated with low  $q_E$ , and that this reflects efficient energy utilization by the Calvin cycle. In our research we found that these three parameters (i.e.,  $F_v/F_m$ ,  $(F_v)_s$ ,  $q_E$ ) are the best correlated with sugarbeet sucrose yield and that high  $(F_v)_s$  is always associated with low  $q_E$  and high root sucrose content.

## 2. 1993 Greenhouse Experiment

During the past year, we sought to optimize the experimental procedure for using pulse-modulated fluorescence to develop new high-yielding genotypes. Our objectives were to: 1) increase the size of the selection sample as well as that of the total population screened, 2) to provide growing conditions which minimized competition between plants for light and nutrients, and 3) to increase the length of time between fluorescence measurement and harvesting (particularly for root sugar content). We carried out the experiment inside a computer-controlled greenhouse which maintains temperatures and irradiance within certain defined limits. This facility enabled us to grow the plants in a single controlled environment, to illuminate the plants at high light intensities (up to  $2000 \text{ umol m}^{-2} \text{ s}^{-1}$ ) and with one plant per 20-L container so that mineral nutrient supply was not limiting.

Two weeks after transplanting, chlorophyll fluorescence of the attached leaves was measured using the pulse modulation chlorophyll fluorometer Model PAM 101 (H. Walz, Effeltrich, FRG). At the end of the fluorescence measurement period (5 days), the 30 plants exhibiting the highest values and the 30 plants with the lowest values of each of the two fluorescence parameters,  $F(v)_s$  and  $F_v/F_m$ , were selected and transferred into 20-L containers. The plants grew significantly faster than in growth chambers and by the end of 6 weeks had reached sufficient size for harvesting.

The 1993 experiment was successful in that we were able to increase the size of the selection sample at screening (increased from 24-27 plants in 1992 to 100 plants in 1993) and

the size of the total population screened (from 195 plants in 1992 to 585 plants in 1993). Furthermore, the new greenhouse enabled us to illuminate the plants at much higher light intensities than in the growth chambers and to eliminate competition for nutrients (one plant per pot, nutrients replaced weekly). The plants were re-randomized in their position in the greenhouse weekly also. We did not need to increase the time from selection to harvest because the plants grew so fast under these conditions. However, the use of the greenhouse facility also brought with it some new difficulties which we did not encounter in the growth chambers. For example, when the young plants (5 weeks from sowing) were transferred to the greenhouse from the growth chamber, they suffered heat shock and wilted severely. Most plants recovered but some were replaced. Then 2 weeks after transplanting, Berkeley experienced an unusual heat wave for about 1 week. This resulted in damage to the faster-growing plants which wilted more readily than the slower-growing, smaller plants. We also experienced fungal infection of the roots which changed the rate of growth of some plants and increased variability.

What did the results from the 1993 experiment show? We selected at the seedling stage for the two fluorescence parameters,  $F(v)_s$  and  $F_v/F_m$ , i.e., we selected plants which exhibited the 30 highest values and the 30 lowest values for each parameter (giving a total of 100 plants). We grew the plants for 6 weeks and measured the storage root sugar yield and % storage root sucrose as well as fresh and dry weights of plant parts. Ten plants which exhibited serious root damage and other defects were eliminated from the analysis. The remaining 90 plants were tested for statistical correlations between root sugar yield, or sucrose %, with  $F(v)_s$  or  $F_v/F_m$  (Table 1). The results show that young

**Table 1. Greenhouse Experiment 1993: Correlation coefficients of fluorescence parameters with important growth and yield attributes of the selected plants**

	St.Rt.F.Wt.	St.Rt.D.Wt.	Rt.D.Wt. %	Sugar %	Total sugar

\*, \*\*, \*\*\* = significant at  $P=0.05$ ,  $P=0.01$ ,  $P=0.001$ , respectively.

plants selected for high  $F(v)_s$  or high  $F_v/F_m$  subsequently exhibited storage roots which had high % sucrose but low total

root sugar yield (Table 1, Figs. 1,2). This finding confirmed last year's results with respect to sucrose % but differed for root sugar yield which was correlated positively with high  $F(v)_s$  or high  $F_v/F_m$  in previous years' experiments (see Reports for 1993, 1992). In this year's experiment, plants selected for high  $F(v)_s$  or high  $F_v/F_m$  had smaller root sizes as indicated by the smaller storage root dry and fresh weight (Table 1).

Other significant correlations were obtained (Table 1). For example, high  $F(v)_s$  or high  $F_v/F_m$  was found to be correlated with high storage root percentage dry matter. When fluorescence parameters other than  $F(v)_s$  or  $F_v/F_m$  were considered, we found that storage root sugar content correlated positively with high values of  $F_v$  and  $q_Q \cdot F(v)_s$  and correlated with low values of  $q_E \cdot F(v)_m$ ,  $q_Q$  and  $q_E$ . Total storage root sugar yield correlated negatively with  $F_o$ ,  $F(v)_m$ ,  $F_v$  and  $F_m$ .

### 3. Field Trial Statistical Analysis

Dr. Harm Schipper (Van der Have) carried out a statistical analysis to see how well fluorescence parameters obtained by the Terry Lab at University of California, Berkeley, correlated with sugar yields in a field trial carried out by Van der Have in The Netherlands. Plants of 39 different seedlots were compared. The objective of Dr. Schipper's analysis was to determine whether high sugar-yielding genotypes exhibited fluorescence characteristics which would identify them as high-yielding genotypes. Dr. Schipper's analysis was exciting because it showed that sugar yield was correlated significantly (in some instances up to  $P = 0.001$ ) with several different fluorescence parameters. The data show that there was a highly significant positive correlation between white sugar yield (WSY) and  $F_o$ ,  $F_m$ ,  $F_v$ ,  $F(v)_s$ , and  $F(v)_m$  (Table 2). Similarly, sugar concentration (SC)

**Table 2. Field Study Analysis: Correlation coefficients among field sugar yield data of 39 seedlots and laboratory-measured fluorescence parameters. $q \cdot F(v)_m$	-0.189	0.157	0.602*

\* = significant at  $P=0.05$  and  $P=0.01$ , respectively.

Dr. Schipper also developed a number of indices by the addition of the values of several fluorescence parameters as follows:

$$\begin{aligned}
A1 &= F_o + F_v \\
A2 &= F_o + F_v + F(v)_s \\
A3 &= F_o + F_v + F(v)_s + F_m + F(v)_m \\
B1 &= q_Q \cdot F(v)_s + q \cdot F(v)_m \\
B2 &= (q_Q \cdot F(v)_s + q \cdot F(v)_m) * q_Q
\end{aligned}$$

These indices were then tested for their correlation with sugar yield from the results of the field trials. When all the 39 seedlots were considered, highly significant correlations were found between WYS and A1, A2 and A3, and between SC and B1 and B2 (Table 5). Similar correlations were also obtained when group 1 and group 2 seedlots were considered separately (Table 5). Figure 3 illustrates how well WSY correlated with the fluorescence index A1.

**Table 5. Field Study Analysis: Correlation coefficients among field sugar yield data and fluorescence indices derived from laboratory-measured fluorescence parameters (see text above for the meaning of these indices)**

#### 4. Conclusions

1) Based on Dr. Schipper's analysis and from our results of this and previous years, there is little doubt that high-yielding sugar beet genotypes can be identified by their fluorescence characteristics.

2) The 1993 greenhouse experiment, which was designed to show that selection for high values of  $F(v)_s$  and  $F_v/F_m$  can predict those plants with high root sugar yields, was successful

Fig. 3: Relationship between fluorescence index A1 ( $A1 = F_O + F_V$ ), measured in our laboratory for young plants of 39 seedlots, and white sugar yield obtained from plants (of the same seedlots) grown in the field in The Netherlands.

in predicting plants with high root sugar concentration (but not sugar yields).

3) The 1993 greenhouse experiment permitted us to increase the sample size at the time of selection and the total size of population screened, and to increase illumination and mineral nutrient supply. However, we also encountered unanticipated setbacks in that plants wilted after transfer from the growth chamber to the greenhouse, suffered damage following an unusual heat wave, and some plants developed fungal infections of their roots. The faster-growing plants were more prone to damage than their slow-growing counterparts and we believe that this, along with increased variability, reduced our chances of obtaining good correlations of sugar yield with fluorescence.

This year we will continue to use the greenhouse to conduct the experiment but we will avoid the difficulties we encountered last year by conducting the whole experiment, from seed germination to harvest, in pots filled with vermiculite and peat moss. By this means we should eliminate transplanting shock, and, root cracking and root fungal infection (in the 1993 experiment, the storage roots cracked when they expanded into the lids of the nutrient solution container; this led to fungal infection). Furthermore, we will attempt to simulate field conditions more precisely by withholding nitrogen from the plants for 2 weeks prior to harvest so that sucrose levels build up in roots. The fluorescence measurements will be carried out in the greenhouse. This will require the use of special adapters to dark-adapt the intact leaves in situ before measuring fluorescence emission under daylight illumination.

Wozniak, C. A. and L. D. Owens. 1994. Native  $\beta$ -glucuronidase activity in sugarbeet (*Beta vulgaris* L.). *Physiol. Plant.* 89: (In press).

$\beta$ -Glucuronidase activity, initially thought absent from plants, has been found in a number of plant families. During an analysis of *Agrobacterium*-mediated transformation of sugarbeet (*Beta vulgaris* L.), significant glucuronidase activity was observed in control (non-transformed) tissues when the fluorogenic substrates 4-methylumbelliferyl- $\beta$ -D-glucuronic acid, resorufin glucuronic acid and 3-carboxyumbelliferyl- $\beta$ -D-glucuronic acid were used to quantify  $\beta$ -glucuronidase activity under standard protocol conditions. Similarly, the colorigenic substrate p-nitrophenyl- $\beta$ -D-glucuronide was hydrolyzed by this sugarbeet-derived glucuronidase. Biochemical and immunological data are presented to indicate significant differences between sugarbeet-derived glucuronidase and that of microbial origin (i.e., encoded by *gusA*; E.C. 3.2.1.31). These differences provide means of distinguishing between the two activities in extracts that contain a mixture of both. Use of X-gluc, the substrate utilized in histochemical localizations of glucuronidase activity, gave no reaction product (i.e., indigo precipitate) at pH 7.0. However, at pH 3.0, 4.0 and 5.0 formation of the indigo precipitate was evident within 1 h at 37 °C in sugarbeet callus and by 4 h in leaves and petioles. The specific activity of sugarbeet glucuronidase was observed to be strongly pH dependent, with an optimum near pH 4.0. The use of various  $\beta$ -glucuronidase assay techniques as applied to transformation of sugarbeet is discussed.

Owens, L. D., R. O. Nordeen, J. B. Philbrick and J. C. Ingersoll. 1993. Design and testing of novel genes for plants to defend against bacterial pathogens. *Abstr. of Papers*, 206th Amer. Chem. Soc. Nat'l Mtg. AGRO 141.

New sources of resistance to microbial pathogens are needed to maintain productivity of agricultural crops. Modern techniques in molecular biology now enable taking a gene from any source, reconstructing it with appropriate regulatory sequences, inserting it into the target plant and having it expressed and inherited as part of the plant genome. This talk will describe investigations to test the feasibility of engineering the cecropin gene from the insect *Hyalophora cecropia* to augment the plant's natural defenses against

pathogenic bacteria. Included will be (1) data on the relative toxicity of cecropin to pathogenic bacteria and to cells of their respective host plants, (2) design and construction of the gene, (3) evidence for expression and heritability of the gene in a model test plant and (4) new physical techniques for inserting genes into plant tissues for rapidly determining how efficiently they will be expressed.

Wozniak, C. A., and L. D. Owens. 1993 Use of  $\beta$ -Glucuronidase (GUS) as a marker for transformation in sugarbeet. J. Sugar Beet Res. (In press).

Accurate quantitation of an introduced genetic or biochemical marker into sugarbeet (*Beta vulgaris* L.) is based on the absence of native activities in the plant that could confound analysis of marker expression. During the course of experiments designed to optimize DNA transfer from *Agrobacterium tumefaciens* to sugarbeet leaf disc cells, an endogenous enzyme activity was discovered which utilizes all the common substrates recognized by the marker enzyme,  $\beta$ -glucuronidase (GUS) from *E. coli*. This native sugarbeet enzyme (SB-GUS) was characterized immunologically and biochemically. GUS and SB-GUS were found to be distinct with regard to pH optima, thermal inactivation, reaction to denaturants and protein modifying reagents, inhibition by metals and saccharo-lactone, and molecular mass. The two activities are not immunologically related, as judged by Western blot and immunoprecipitation analyses. A protocol was developed to accurately quantitate introduced GUS in the presence of SB-GUS, by utilizing selective inhibition of GUS at pH 7.0 by saccharic acid 1,4-lactone. Under these conditions GUS activity is completely eliminated, while SB-GUS activity was unaffected.

## BSDF Project 800

J. C. Ingersoll and L. D. Owens

### Expression of cecropin gene in transgenic tobacco plants -

Cecropins are a family of small polypeptides (~40 amino acids in length) that possess potent antibacterial activity against many bacteria, including a number of plant pathogens. A synthetic version of cecropin B, consisting of the coding region of cecropin fused to the secretory sequence from barley  $\alpha$ -amylase and placed under control of two different promoters, was introduced into the model test plant tobacco. The promoters used were the enhanced 35S (En35S) promoter from cauliflower mosaic virus and the proteinase inhibitor II (PI-II) promoter from potato.

Preliminary challenge experiments using *Pseudomonas solanacearum* infection of either wounded roots or punctured stems indicated delayed symptom development with the PI-II but not the En35S promoter. Because these experiments occurred over a period of many months, and because many R0 plants challenged with the En35S construct were lost, a new set of transgenic *Nicotiana tabacum* cv. Bottom Special were produced and vegetatively cloned. One set of cloned lines is being challenged by infiltration of different numbers of *Pseudomonas syringae* pv. *tabaci* into leaves. The leaves are scored for chlorosis/necrosis symptom development, and leaf discs are punched from replicate infection loci for bacterial counts. Preliminary results with PI-II-cecropin transgenic plants indicate protection at normal levels of infection.

**Promoter analysis in sugarbeet cells** - Engineered defense genes need to be efficiently expressed in the target plant. In order to study the efficiency of inducible promoters and accompanying 5'-untranslated leader sequences in sugarbeet, various combinations of these elements were fused to the *gusA* gene coding region and used to coat gold microbeads. Previously, these DNA-coated beads were shot into detached sugarbeet leaves to ascertain transient GUS expression. The leaf system, however, gave low numbers of GUS<sup>+</sup> (blue) foci and was highly variable.

To develop a more consistent promoter-analysis system, sugarbeet suspension cell cultures were established from leaf-disc callus. Basically the system consists of layering a fine suspension of cells on a membrane, bombarding the cells with DNA-coated beads, culturing for 24 h to allow expression of the promoter-*gusA* construct and assaying for GUS

expression. The histochemical substrate X-gluc was used in optimization studies. The number of blue foci obtained is an indication of expression efficiency. Highest efficiency was obtained when cells were: layered at a rate of 12 mg FW/cm<sup>2</sup> of membrane (cellulose nitrate or nylon) using a filtration apparatus; precultured for 4 h on medium supplemented with an osmoticum (0.25 OsM consisting of equal amounts of mannitol and sorbitol); bombarded with particles propelled by 1350 psi He at a distance of 10 cm; and postcultured 24 h on the same high-osmotic medium. The membrane and cells were then transferred to filter paper wetted with X-gluc solution and 30 mM ascorbate (to prevent browning) and incubated overnight at 37 °C. These optimized conditions are being used to analyze promoter-*gusA* constructs prepared with promoters derived from the wound-inducible genes osmotin, PR-S and PI-II and the constitutive En35S promoter.

## GENE TRANSFER AND CLONING RELATED TO SUGAR PARTITIONING

G. W. Snyder and L. D. Owens

**Gene transfer to sugarbeet** - Transgenic sugarbeet plants were obtained by coculture of leaf discs with an *Agrobacterium* vector strain. The method used was that described in a French patent held by Le Groupe Limagrain (contact made through Tom Schwartz). Proof of transformation was indicated by growth on kanamycin, strong GUS activity of excised leaf pieces and PCR analysis of DNA. Several defense-gene constructs are currently being introduced.

**Cloning of sucrose phosphate synthase gene** - A key gene known to exert a major influence in sugar production and export from tomato leaf is the sucrose phosphate synthase (SPS) gene. When a heterologous SPS gene is introduced, the resulting SPS enzyme is less controlled by feedback inhibition mechanisms, and more sucrose is exported from the leaves. We have cloned, in segments, about 3/4 of the SPS gene from maize by PCR techniques. The plan is to place the entire coding region of this gene under control of a taproot-expressed promoter and introduce the construct into sugarbeet.

### Abstract of Paper Approved for Publication

Ruppel, E. G. and R. J. Hecker. 1994. Rhizoctonia root rot on sugarbeet cultivars having varied degrees of resistance. J. Sugar Beet Res. 31:(in press)

To address a concern that yield losses may be greater in resistant than in susceptible sugarbeet cultivars, five cultivars, including a susceptible and two moderately resistant commercial varieties, a resistant three-way experimental hybrid, and a highly resistant breeding line, were tested in the field in 1989, 1990, and 1991 for their reaction to inoculation with *Rhizoctonia solani* (AG-2-2). Generally, rankings of the cultivars for percent decreases (inoculated versus noninoculated) in root and recoverable sucrose yield and percent sucrose and percent purity tended to be proportional to disease severity indices. With the exception of percent purity in 1990, positive significant or highly significant coefficients of linear correlation between disease index differences (inoculated versus noninoculated) and percent decreases in yield and purity parameters each year indicated that there were no hidden losses to *Rhizoctonia* root rot in resistant germplasms.

RHIZOCTONIA ROOT ROT RESEARCH AND DEVELOPMENT OF  
GENETIC RESISTANCE IN SUGARBEET  
(BSDF Project 402)

1993 Field Research on Rhizoctonia Root Rot of Sugarbeet.--E. G. Ruppel and L. W. Panella.

We have been pleased to lead this cooperative research project of ARS, the BSDF, and the Colorado Agricultural Experiment Station. Our project primarily involved field studies conducted on the Colorado State University South Campus in an area reserved for Rhizoctonia root rot research.

The 1993 field experiments were planted in an area that had been in barley for 3 years and was the site of our inoculated Rhizoctonia nursery in 1989. No Rhizoctonia root rot occurred from residual fungus before inoculation of sugarbeet in 1993. Our 4-year rotation with barley apparently is sufficient for the degradation of *Rhizoctonia*-infected residues in our soils of low organic content.

Rhizoctonia evaluation experiments were planted in one-row plots 56 cm (22 in) apart and 4.3 m (14 ft) long. Experiments were planted in mid-May and thinned to a 20- to 25-cm (8- to 10-in) in-row spacing the third week of June. Dry, ground, barley-grain inoculum of *Rhizoctonia solani* (isolate R-9) was banded over the rows on July 19 at a rate of 8.4 g/4.3-m row with a tractor-mounted four-row granule applicator. Inoculum was banded in a split application, with opposite directions of travel for each application. Immediately after inoculation, we performed a cultivation designed to throw soil into sugarbeet crowns, a practice that we previously identified as being conducive to the development of root and crown rot. Our standard sprinkler irrigation regime was used to moisten and activate the inoculum. Succeeding irrigations were done by furrow. Before field inoculation, we tested inoculum for virulence on 2-mo-old sugarbeets in the greenhouse; our 1993 inoculum was highly virulent, rotting all inoculated plants.

Roots in all experiments were lifted either the last week in September or the first week in October and individually rated for rot on a disease index (DI) scale of 0 to 7, with 0 = no evidence of rot and 7 = plant dead. Percent healthy roots were those with DIs of 0 and 1, roots with no active infection. Roots with DIs 0 through 3 also were analyzed as a class; these roots were sufficiently sound and large to be recovered in a commercial harvest.

Due to the cool, wet summer, our 1993 epidemic of root rot was rather mild, although more intense than our 1992 epidemic. In the critical months of July through September, night low temperatures never exceeded 51°F, and day temperatures also were unseasonably low. With one exception (week four in August), we experienced a departure of -1 to -7 degrees from the 70-yr mean weekly temperature. By the end of September, we were 200 growing-degree-days below the year-to-date 70-yr mean temperature. Thus, our susceptible check mean DI was 2-3 classes below the average of 6-7. Nevertheless, the procedure of throwing soil into the crowns provided adequate contrasts among entries. Mean DIs across all tests for highly resistant, resistant, and susceptible checks were 1.7, 1.8, and 4.2, respectively.

## Testing of materials developed by R.J. Hecker.--L. Panella, E. G. Ruppel and R. J. Hecker (retired).

Genetic information developed previously in our research was used for additional cycles of pathogen inoculation, plant selection, and recombination among germplasms that we have in our cyclic improvement program. Germplasms in various stages of improvement were evaluated for resistance in inoculated field tests. Results of these tests were the basis of decisions about specific germplasm, i.e., retain, shelve, discard, recombine, release, register, etc. Germplasms likely to be useful for variety improvement were identified and released for use by other sugarbeet breeders.

We are continuing to field-evaluate lines developed in the breeding program of Dr. R. J. Hecker. Thirteen lines were field-tested in 1993 for resistance to *Rhizoctonia solani*, *Cercospora beticola*, and the curly top virus (Table 1). Seed was increased from three lines, FC709(4X), FC710(4X), and FC712(4X), that were converted to tetraploidy (4X) with colchicine treatment. They are lines that previously were released from the Fort Collins program as diploids (2X), with good combining ability and high resistance to *Rhizoctonia* root rot. Additional lines developed in Dr. Hecker's program were increased in isolation plots in 1993.

Lines that showed outstanding performance in 1993 field trials will be released in 1994 or 1995. One of the tetraploids, along with a few other lines increased in 1993, will be tested in the summer of 1994 and the best of these lines released.

## Base Populations to Develop Multiple Disease Resistance.--L. Panella.

In a hybrid crop like sugarbeets, it is preferable that all of the parents contain some level of resistance to diseases prevalent in the area in which the hybrid is to be grown. Multiple disease resistance is a difficult goal in a crop improvement program, especially when working with an outcrossing species. In alternating generations of selection, some of the progress made in resistance to one disease is lost while selecting for resistance to other diseases.

One way of solving the problem of selecting for multiple disease resistance is the use of progeny testing. By testing the progeny of individual mother roots, plants with multiple disease resistance can be identified and used as parents of the next generation. The most efficient use of progeny testing is when the genotype of both parents is known, and the easiest way to do this is through self-pollination. In sugarbeet, the dominant, self-fertility allele permits self-pollination. Used in conjunction with genetic male sterility to insure cross pollination, a system of full-sib progeny testing can be utilized.

Material from the USDA-ARS breeding program at Salinas, CA, has been crossed with some of the Fort Collins lines most resistant to *Rhizoctonia solani*. The Salinas material had the self-fertility allele, was segregating for genetic male sterility, and also contained a broad spectrum of resistance to diseases of importance in California as well as other sugarbeet production areas (including rhizomania, powdery mildew, virus yellows, curly top virus, and cyst nematode). Crosses were made reciprocally (with some plants from each line as females and some as males) when possible. The genetic male sterile plants in the Salinas lines were used as females, and red (R\_) and green (rr) hypocotyl color were used

as markers (if possible) when the Fort Collins material was used as a female ( $\sigma$  = R\_ and  $\eta$  = rr; only progeny with a red hypocotyl will be used). We also examined the possibility of using isozyme markers or RFLP markers when the plants with the correct hypocotyl color were not available.

Table 1. The performance in three disease nurseries of previously released Fort Collins (FC) germplasms and thirteen lines being considered for release.

Source	Designation	Disease indices		
		Curly top	Leaf spot	Rhizoctonia

Resistant check <sup>2</sup>		4.7	4.5	1.2
Highly resistant check <sup>3</sup>				1.3
LSD		NS	1.1	0.4

<sup>1</sup>Susceptible check: curly top = US33, leaf spot = LSS synthetic, Rhizoctonia = 831044.

<sup>2</sup>Resistant check: curly top = US41, leaf spot = 821051H2, Rhizoctonia = FC703.

<sup>3</sup>Highly resistant check: Rhizoctonia = FC705-1.

Five lines from the Salinas breeding program, grown in the steckling field, were crossed with two lines from the Fort Collins program. Both multigerm pollinators

and monogerm, 0-type maintainers were used (Table 2). Neither isozyme analysis nor the use of RFLPs, obtained from restricting the ITS region in the rDNA region (Figure 1), provided enough discrimination to distinguish hybrid progeny in the crosses between Fort Collins and Salinas material. This provides some indication of the lack of genetic diversity among cultivated sugarbeet populations used in this country.

Table 2. The parents to be used in reciprocal crosses to establish *Rhizoctonia* resistant base populations.

Line	Origin	Comments
FC708	Fort Collins	<i>Rhizoctonia</i> resistant 0-type
921024	Fort Collins	<i>Rhizoctonia</i> resistant Multigerm
93A001	Salinas	2915, Multigerm segregating for self-fertility and male sterility
93A002	Salinas	R278, Multigerm, self-fertile segregating for genetic male sterility
93A003	Salinas	2890, segregating for 0-type, self-fertility and genetic male sterility
93A004	Salinas	N244, Multigerm segregating for self-fertility and male sterility
93A005	Salinas	2859, 0-type segregating for self-fertility and genetic male sterility

The Salinas lines from the steckling field will be crossed to the Fort Collins disease-resistant lines and the  $F_1$  populations intracrossed ('selfed'). The resultant populations, together with the materials from Dr. Hecker's program, eventually will form the basis of a *Rhizoctonia* breeding project, containing a strong laboratory component. This program will focus on understanding the genetics of the *R. solani*-sugarbeet interaction, increasing selection efficiency for resistance to *Rhizoctonia* root rot, and producing multiple disease resistant sugarbeet germplasms.

#### Genetic Variation and Pathogenicity in *Rhizoctonia solani*.--L. Panella and M. K. Hjort.

Currently, it is possible to assay the pathogenicity to sugarbeet of an isolate of *R. solani* through a greenhouse bioassay only, which may take 12 to 16 weeks. Although there has been recent work done on the phylogenetics of this pathogen, evolutionary relationships among isolates have not been well correlated with the host specificity of the fungus. Whether the pathogenicity to sugarbeet has evolved once or more than once could substantially influence the types of host-pathogen interactions.

*R. solani* is divided into anastomosis groups (AGs) based on the ability of the hyphae to fuse and exchange genetic material, or, more recently, into

intraspecific groups (ISGs) based on molecular markers, especially the internal transcribed spacers (ITS) flanking the 5.8S ribosomal RNA gene (rDNA) (Figure 1). Isolates of *R. solani* from AG-4 cause seedling damping-off in sugarbeet, and isolates from AG-2-2 cause root and crown root in mature beets.

We are using PCR to amplify the DNA of *R. solani* coding for the 5.8S ribosomal RNA gene (rDNA) as well as the two flanking ITS regions. This will be done with the ITS1 and ITS4 primers (Figure 1) (Lee & Taylor, 1990). Restriction enzymes that recognize four base-pair sites are being used to create restriction fragment length polymorphisms (RFLPs) from the amplified DNA. We will use these RFLP markers to identify ISGs within AG-2-2. Isozyme markers may also be used to further discriminate ISGs. The *R. solani* isolates then will be tested for their virulence in sugarbeet. The phylogenetic information will be correlated with the pathogenicity data to see if all the isolates pathogenic to sugarbeet belong to the same evolutionary group. In any case, the sugarbeet-pathogenic group(s) will be delineated with genetic markers.

Currently, DNA from 42 isolates of *R. solani* has been amplified and cut with five restriction enzymes. Some RFLPs were detected with these enzymes, as well as initial differences in the size of the amplified length of DNA, which varies from approximately 700 to 750 base pairs (BPs).

Forty to 60 more isolates of *R. solani* pathogenic to sugarbeet are being obtained from diverse locations. They will be analyzed in a similar fashion to the original 42. The DNA will be separated on agarose gels, visualized with ethidium bromide, and photographed. We will use the enlarged photographs to estimate the fragment sizes, using markers of known size (from a *Hae*III digest of  $\Phi$ X174RFI). More enzymes will be used as needed to discriminate among the various ISGs in the different anastomosis groups. Greenhouse tests will be used to determine the pathogenicity of the isolates of *R. solani* to sugarbeet. These data will be correlated with the phylogenetic information.

Figure 1.

## EVALUATION OF CONTRIBUTED LINES FOR RESISTANCE TO RHIZOCTONIA ROOT ROT (BSDF Project 903)

We used randomized complete-block designs with five replications to evaluate a total of 173 lines from six companies; additionally, one company had a second test of 12 lines replicated three times. Rhizoctonia resistant FC703 and highly susceptible FC901 were included as internal controls, along with highly resistant FC705-1. Experimental design, plot size, and evaluation method are described in the section "1993 Field Research on Rhizoctonia Root Rot of Sugarbeet." The experimental design, methods, results and statistical analyses were provided to the appropriate company breeders.

Our 1993 root rot epidemic was milder than normal due to a cool, wet summer, but more severe than in 1992. Mean DIs across all tests for highly resistant FC705-1, resistant FC703, and highly susceptible FC901 were 1.7, 1.8, and 4.2, respectively, compared with 0.7, 0.8, and 1.3, respectively, in 1992. Percent healthy roots were 53.0, 49.2, and 8.9 for these controls, respectively; percentages of roots in disease classes 0 through 3 were 97.7, 98.0, and 60.3, respectively. The lowest and highest mean DIs for contributor lines across tests were 1.4 and 5.4, respectively, compared with 0.5 and 2.9 in 1992.

## EVALUATION OF CONTRIBUTED LINES FOR RESISTANCE TO CERCOSPORA LEAF SPOT (BSDF Project 904)

We used randomized complete-block designs with three replications to evaluate 214 lines from six contributors. Internal controls included a highly susceptible synthetic and a resistant check, FC(504 X 502/2) X SP6322-0. Two-row plots were 4.3 m (14 ft) long, with 56 cm (22 in) between rows and a 20- to 25-cm (8- to 10-in) within-row spacing. We inoculated twice (June 29 and July 7).

The 1993 leaf spot epidemic progressed slowly due to our cool summer (see "1993 Field Research on Rhizoctonia Root Rot of Sugarbeet," these reports). Although disease severity by early September was not as great as in previous years, we made our first evaluations on September 7. That afternoon, we had a short, but extremely hard hail storm, which was followed by two nights of severe frost. At our second rating date (September 14), the leaves were severely tattered from the hail, and there was much frost damage. I decided that further evaluations would be useless.

On September 7, means of the resistant and susceptible checks across the nursery were 2.7 and 4.4 (scale of 0-10), respectively. In 1992, these means on September 17 were 4.1 and 6.7. Means of contributor lines ranged from 2.0 to 5.0 on September 7, and 3.0 to 6.0 at the later date. In 1992, means on September 17 ranged from 3.2 to 7.3. Means of contributor tests were tabulated, statistically analyzed, and sent to the appropriate contributor.

BUGBEE, W. M. 1993. *Rhizoctonia*-induced phytoalexin production in sugarbeet. *J. Sugar Beet Res.* 30:83.

Resistance of sugarbeet to *Rhizoctonia solani* increased with age. The shift from susceptibility to resistance occurred about three weeks after planting and was accompanied by the production of phytoalexins. Three-week-old plants produced more phytoalexin when infected by the AG 4 strain than when infected by the AG 2-2 strain of *R. solani*. At five weeks, more phytoalexin was induced by AG 2-2 than AG 4. AG 4 was more sensitive than AG 2-2 to phytoalexin, which may partially account for the avirulence of AG 4 on older plants. When root slices were inoculated with *R. solani*, more phytoalexin was produced by the susceptible cultivar Ultramono than the resistant germplasm FC 712. The AG 4 strain induced more phytoalexin than AG 2-2, but neither was significantly different than untreated controls. *R. solani* cultures with pectin from Ultramono as the only carbon source contained more phytoalexin elicitors than cultures of FC 712 pectin. AG 2-2 induced more elicitors than AG 4, but neither induced more than the uninoculated control. Pectic fragments appeared to be weak elicitors of phytoalexins. Thus phytoalexins were associated with age-related resistance but not varietal resistance. Pre-formed antibiotics were present in ethanol extracts of root.

CAMPBELL, L. G. and A. W. ANDERSON. 1993. Additional sources of resistance to sugarbeet root maggot. *Annual Plant Resistance to Insects Newsletter* 19:18.

Selection for resistance to the sugarbeet root maggot (*Tetanops myopaeformis* Röder) has been marginally successful. While it seems apparent that one can develop sugarbeet (*Beta vulgaris* L.) lines with a moderate and perhaps useful level of resistance, the difficulty of selecting under natural infestations and mode of inheritance hinder the incorporation of sugarbeet root maggot (SBRM) resistance into commercial hybrids. Because of this, new and more effective resistance genes are especially needed in the SBRM breeding program. The Sugarbeet Crop Advisory Committee (CAC) has sponsored a SBRM screening effort at St. Thomas, North Dakota since 1987. Data has been compiled on 170 accessions of the NC-7 *Beta* collection (USDA-ARS, Ames, Iowa) and is available on the USDA Germplasm Resources Information Network (GRIN). The following 17 accessions have been characterized as having at least an intermediate level of SBRM resistance and will be reevaluated: PI-165485, PI-232887, PI-266100, PI-266104, PI-274394, PI-285589, PI-285590, PI-285594, PI-286502, PI-293419, PI-355962, PI-357357, PI-467869, PI-467870, PI-467871, PI-467874, PI-467875. All 17 are biennials; nine are sugarbeet types and the remainder table

beets. The resistance of two accessions identified in an earlier screening, PI-179180 and PI-181718, has been confirmed. These two accessions incur damage similar to the most resistant lines in our breeding program. Crosses have been made to transfer this resistance into agronomically useful populations and to study the inheritance of resistance. The CAC screenings included species related to sugarbeet. Although only a few *B. patellaris* accessions have been examined, all exhibit a high level of resistance. Unfortunately, crosses between this species and sugarbeet are not easy.

CAMPBELL, L. G., A. W. ANDERSON, and K. A. PRODOEHL. 1993. The use of exotic and domestic germplasm for resistance to the sugarbeet root maggot. *J. Sugar Beet Res.* 30:84.

The sugarbeet root maggot (*Tetanops myopaeformis* Röder) is a major insect pest of sugarbeet (*Beta vulgaris* L.). Attempts to develop resistant genotypes have been marginally successful. Breeding lines provide control comparable to that obtained with insecticides. However, the difficulty of selection and the mode of inheritance make it difficult to incorporate maggot resistance into a commercial hybrid development program. Past breeding efforts have utilized mass selection under natural maggot infestations. Alternative methods being explored include selection based upon family performance and the conversion of resistant germplasm to a tetraploid line for testing as a pollinator parent. Portions of the NC-7 *Beta* collection (USDA; Ames, Iowa) have been screened for maggot resistance. PI179180 and PI181718 have confirmed resistance. Both are biennial with red globe-shaped roots. Seventeen biennial *B. vulgaris* accessions identified as resistant in initial screenings are being increased for further evaluation. A 0 to 9 damage rating scale was utilized to differentiate among breeding lines more efficiently than the widely used 0 to 5 scale.

CAMPBELL, L. G. and W. M. BUGBEE. 1994. Pre-breeding for root-rot resistance. *Proc., Third International World Beta Network Conference*, Fargo, ND, August 4-6, 1993.

A number of crown and root rot diseases reduce yield in sugarbeet. Many of these diseases are limited to small geographic areas and their incidence is often sporadic. Hence, development of resistant cultivars has not been a high priority. Rhizoctonia, Aphanomyces, and Erwinia root rots are exceptions. Commercially useful resistance to *Rhizoctonia* and *Aphanomyces* originated from only a few sources. *Erwinia* resistance is available from numerous sources and is relatively easy to select for. Selection for resistance to prevalent storage rot fungi is possible but has not received much attention from commercial sugarbeet breeders. Knowledge of the inheritance of root or storage rots is frequently incomplete and sometimes inconsistent. Results of systematic screenings of the USDA *Beta* collection confirm the scarcity of resistance to *Rhizoctonia* and *Aphanomyces* and the difficulty of broadening the currently narrow genetic base of sugarbeet. Genetic engineering techniques probably will not make a contribution to the development of root rot resistant germplasm in the near future. Understanding

the biochemical basis of resistance will eventually improve selection efficiency and hasten the application of genetic engineering technologies to the problems of host plant resistance.

CAMPBELL, L. G. and A. W. CATTANACH. 1993. Effects of a foliar applied cytokinin on sugarbeet. *J. Sugar Beet Res.* 30:83.

There have been numerous attempts to increase crop productivity through the manipulation of plant hormones. Although this research has encompassed a wide variety of crop species, environments, and objectives, growth regulator (hormone) usage remains minimal in field crop production; sugarbeet (*Beta vulgaris* L.) is no exception. Cytokinins are known to influence a number of plant processes including cell division and enlargement, suggesting an influence upon sugarbeet root size and sucrose concentration. Seven rates of a cytokinin containing plant growth regulator (TRIGGRR; Westbridge Agricultural Products, San Diego, CA) were applied to sugarbeets in the 2-, 4-, and 6-leaf stage. Root yield, sucrose concentration, and recoverable sucrose yield were measured in 1989-1991 field trials. Storage respiration rate and response to two storage rot fungi (*Phoma betae* (Oud.) Frank and *Botrytis cinerea* Pers. ex Fr.) were measured in 1990 and 1991. Field plots were established using conventional tillage practices in Cass County, ND. Significant year effects for all traits were a reflection of differences in growing season weather conditions. Recoverable sucrose yields in 1989 were 30% less than 1990 yields. Nonsignificant treatment effects for all traits suggested that either foliar applied TRIGGRR does not enhance sugarbeet productivity or that it should be applied differently. Nonsignificant year X application rate interactions for all characters indicated this response was consistent in all three years.

DONEY, D. L. 1993. Wild beet in Egypt. *J. Sugar Beet Res.* 30:89.

The wild beets of Egypt are considered to be some of the most primitive. Because of the long history of farming in Egypt, it was anticipated that few wild types would be found. On the contrary, many were found, due mainly to their use as a leaf vegetable by local farmers. Collections were made at selected locations scattered throughout the Delta area, west to Matruh, in the Fayyum area of Middle Egypt, and in the Luxor area of Upper Egypt. A more intensive collection effort was made around the Alexandria area. A total of 26 locations were sampled. Wild beets appear to be distributed throughout the Delta. They were more sparsely distributed in the Fayyum and Luxor areas, where farmers were found collecting and growing wild beets as a green vegetable. In these areas, the farmers are serving as a means of preserving the wild *Beta* germplasm; however, their actions may have exerted selection pressure for leaf type beets.

DONEY, D. L. 1994. Broadening the genetic base of sugarbeet. 1993. *Proc., Third International World Beta Network Conference*, Fargo, ND, August 4-6, 1993.

The narrow base from which sugarbeet originated, the need for disease resistance and the negative relationship between root yield and sugar accumulation have all contributed to make the current gene pool from which most present-day sugarbeets originate narrow. Of the wild germplasm available, *Beta vulgaris* subspecies *maritima* offers the greatest promise of broadening the genetic base for future sugarbeet improvement. Crosses between *B. maritima* and sugarbeet male sterile inbreds have been advanced through four successive cycles of mass selection for root shape. Two of these crosses are approaching sugarbeet in root shape, root yield and sucrose concentration; however, they are still below commercial sugarbeet hybrids in root yield and sugar concentration. Even though these populations are inferior to commercial sugarbeet hybrids, it is the author's belief that superior combining germplasm exists in some of this material and that combining these with commercial germplasm will produce superior hybrids. Additional populations (crosses between sugarbeet and regional populations of *B. maritima*) are in the developmental stage. Sugarbeet inbreds segregating for mendelian male sterility were used in the initial crosses to insure crossing and recombination in each selection cycle.

DONEY, D. L. and R. J. MARTENS. 1994. Selection for Delayed Leaf Senescence in Sugarbeet. *J. Sugar Beet Res.* (in press).

Sugarbeet growth is characterized by the continuous dying of old leaves and initiation of new leaves. If the photosynthetic activity of leaves can be extended, fewer leaves may be needed and more photosynthate can be translocated to the root for sucrose production. Two cycles of divergent selection for early and late senescence of the first leaf were conducted in a very heterogeneous population. Significant genetic changes in each direction were obtained for the green leaf duration of the first leaf. Populations produced from the two cycles of divergent selection were evaluated for their effects on canopy in replicated multi-harvest field trials. The early senescing populations had significantly more and smaller leaves than the late senescing populations but equal total leaf area. Root and canopy dry matter were not affected by selecting for extended leaf duration, but selection for reduced leaf duration reduced root dry matter and total dry matter accumulation.

EIDE, J. D. and G. A. SMITH. 1993. Characterization of pathogenesis related proteins in *Cercospora* leaf spot susceptible and resistant leaf tissue. *J. Sugar Beet Res.* 30:91.

Understanding the nature of *Cercospora* resistance on a molecular basis should certainly enhance our ability to control this destructive fungus. The PR proteins are known to be synthesized in response to *Cercospora* infection. The objective of this study is to determine the presence of these proteins and what roles they

play in *Cercospora* resistance. The PR protein chitinase was isolated from leaf spot susceptible (LSS) and resistant (LSR) leaf tissue. Chitinase activity was determined spectrofluorometrically by measuring 4-methyl-umbelliferone released from the substrate 4-methylumbelliferyl- $\beta$ -D-N,N'-diacetyl-chitobiocide. Six-week-old sugarbeet LSR leaves had 138% higher levels of chitinase activity than LSS leaves. Chitinase from leaf tissue was purified using ammonium sulfate precipitation followed by a chitin affinity method. The apparent molecular weight of the chitinase was 34 kDa as determined by polyacrylamide gel electrophoresis. Purified chitinase extracts will be used to check for inhibition of *Cercospora* fungal growth.

SMITH, G. A. The theory of pre-breeding. 1994. *Proc., Third International World Beta Network Conference*, Fargo, ND, August 4-6, 1993.

Population changes and their dependent gene frequencies are affected by mutation, selection, random fluctuations, meiotic drive, and migration. The effects of selection pressure on relatively small populations can have dramatic effects on gene frequency and hence on breeding progress. This selection, driven by necessity, has resulted in "narrow base" sugarbeet populations. This paper presents examples of population changes which can occur (have occurred in sugarbeet) in populations subject to intense selection. The utility of gene frequency analysis and its use as a predictive tool is outlined. Sugarbeet breeders, geneticists, and agronomists now attempting to collect and introgress wild germplasm into breeding populations will be aided by attention to principles presented in this paper.

SMITH, G. A., C. A. WOZNIAK, L. G. CAMPBELL, and J. D. EIDE. 1993. Evaluation of entomopathogenic nematodes for control of *Tetanops myopaeformis*, the sugarbeet root maggot. *J. Sugar Beet Res.* 30:116.

Nematodes which attack insects (not to be confused with those that affect plants) may offer a biological control for the sugarbeet root maggot (SBRM). They have a broad host range, can be easily mass produced, possess the ability to seek out and rapidly kill their host, are environmentally safe, and have been exempted from registration by the U.S. Environmental Protection Agency. The soil offers an excellent site for insect-nematode interaction, and soil is the natural reservoir of steinernematid and heterorhabditid nematodes. To determine the feasibility of potential nematode use for control of the sugarbeet root maggot, we asked the following: (1) Will nematodes infect the SBRM? (2) Will nematodes reproduce following infection? (3) Can nematodes be applied in the field and be infective? (4) If nematodes are infective in the field, how long will they persist? (5) Will nematodes infect and reproduce in adult flies? We evaluated six strains of nematodes in the laboratory and found that all strains infected, killed, and reproduced in the SBRM larvae. Mortality of the root maggots ranged from 50 to 85 percent in the laboratory. Death of the larvae occurred 24 to 48 hours after

nematode infection. Reproduction within the larval cadavers produced several thousand infective juvenile nematodes 12 to 14 days after infection. Our first-year field tests, conducted in the summer of 1992, indicated that all strains tested infected the larvae in the field. Further laboratory tests determined that adult flies were infected after only two hours of exposure to the nematodes and that reproduction did take place in adult fly cadavers. The results of our investigation show the potential of pathogenic nematodes as a biological control agent for SBRM.

WOZNIAK, C. A. 1993. Influence of native microflora on *in vitro* larval development of *Tetanops myopaeformis* Roder (Diptera:Otitidae). *Proc. North Central Branch Mtg. Ent. Soc. Amer.*, p. 47.

Transmission of endogenous bacteria between generations of the sugarbeet root maggot (SBRM) is via externally carried microflora. Bacteria are transferred to the surface of the chorion during oviposition and transmitted to the first instars upon emergence from the egg sheath. Eggs treated with 0.2% hypochlorite were found to produce gnotobiotic larvae when reared on Luria-Bertani agar or Murashige and Skoog (MS) plant tissue culture medium. Gnotobiotic larvae coincubated on MS medium with axenic sugarbeet cells or roots were observed to feed on the tissue but failed to moult or increase in size. Death of these larvae typically ensued in less than 50 days, at which point they remained as first instars. Addition of *Xanthomonas maltophilia* (Xm), a bacterium isolated from natural populations of SBRM, at the onset of the coincubation with sugarbeet cells resulted in up to 50% of the larvae reaching the second or third instar stage. At the termination of the culture period, the relative amount of remaining sugarbeet tissue was greatly decreased in the presence of Xm and SBRM versus gnotobiotic SBRM. Comparisons of other isolates of Xm and other bacterial species suggests that the capacity to enhance insect utilization of the sugar beet cells is not limited to this one strain of Xm. This coincubation method may eventually serve as a production method for this maggot as they have been recalcitrant to routine lab rearing.

WOZNIAK, C. A. 1993. Culture of sugarbeet root maggots in sugarbeet cell cultures. *Annual Plant Resistance to Insects Newsletter* 19:18-19.

Axenic root cultures of sugarbeet cultivars 'REL-1', 'H5135' and 'MONOHI' were evaluated for their ability to support *in vitro* growth of gnotobiotic sugarbeet root maggots, *Tetanops myopaeformis* Roder (SBRM). 'REL-1' and 'H5135' were also tested as hairy root transformants resulting from transformation of hypocotyl explants using *Agrobacterium rhizogenes*. Surface disinfested SBRM eggs were allowed to hatch in the presence of these root cultures on Murashige and Skoog (MS) tissue culture medium. Many first instars survived longer than four weeks but all failed to moult. Similarly, first instar SBRM cultured on axenic suspension cells of 'REL-1' or 'EL48' were observed to feed and grow but

few (8%) moulted. Those advancing to the second instar stage soon succumbed without further development. Addition of *Xanthomonas maltophilia* (Xm), isolated from SBRM third instar larvae, enhanced moulting percentage to 35 % of the total, and several larvae reached the third and final instar stage. This bacterium survived on MS medium in the presence of sugarbeet cells but grew very slowly on this minimal medium. The amount of remaining sugarbeet tissue following incubation in the presence of SBRM and Xm was greatly reduced compared to SBRM cocultured with sugarbeet cells only.

WOZNIAK, C. A. and S. E. HINZ. 1993. Native bacterial flora and development of larvae of the sugarbeet root maggot. *J. Sugar Beet Res.* 30:123.

Collections of third instar sugarbeet root maggots (SBRM), *Tetanops myopaeformis* Röder, were made in 1991 and 1992 from the Red River Valley, eastern Montana, north central Wyoming, and western Nebraska to determine the identity of bacteria associated with this larval stage. The most commonly encountered species were *Serratia marcescens*, *S. liquefaciens*, *Pseudomonas fluorescens*, *Ps. putida*, and *Xanthomonas maltophilia*. Of these, *X. maltophilia* (Xm) was the only species encountered consistently from third instars regardless of origin. Additionally, Xm was found to be a commensal of the sugarbeet rhizosphere. Bacteria naturally associated with SBRM are transferred to the surface of the chorion during oviposition and transmitted to the first instars upon emergence from the egg sheath. Eggs treated with 0.2% hypochlorite were found to produce gnotobiotic larvae. Gnotobiotic larvae coincubated on MS plant tissue culture medium with axenic sugarbeet cells were observed to feed on the tissue but failed to moult or increase in size. Death of these larvae typically ensued in less than 50 days, at which point they remained as first instars. Addition of Xm (isolated from natural populations of SBRM) at the onset of the coincubation with sugarbeet cells resulted in up to 50% of the larvae reaching the second or third instar stage. At the termination of the culture period, the amount of remaining sugarbeet tissue was greatly decreased in the presence of SBRM with Xm versus gnotobiotic SBRM without Xm. Comparisons of other isolates of Xm and other bacterial species suggests that the capacity to enhance insect utilization of the sugarbeet cells is not limited to this one strain of Xm. This coincubation method may eventually serve as a production method for this maggot as they have been recalcitrant to routine lab rearing.

WOZNIAK, C. A. and L. D. OWENS. 1994. Use of  $\beta$ -glucuronidase (GUS) as a marker for transformation in sugarbeet. *Proc., Third International World Beta Network Conference*, Fargo, ND, August 4-6, 1993.

Accurate detection of an introduced genetic or biochemical marker into sugarbeet (*Beta vulgaris* L.) is based on the absence of native sequences or activities in the plant that could confound the analysis of the introduced marker expression. During the course of experiments designed to optimize DNA transfer from

*Agrobacterium tumefaciens* to sugarbeet leaf disc cells, an endogenous enzyme activity was discovered which utilizes all the common substrates recognized by the marker enzyme,  $\beta$ -glucuronidase (GUS) from *E. coli*. This native sugarbeet enzyme (SB-GUS) was characterized immunologically and biochemically. GUS and SB-GUS were found to be distinct with regard to pH optima, thermal inactivation, reaction to denaturants and protein modifying reagents, inhibition by metals and saccharo-lactone, and molecular mass. The two activities are not immunologically related, as judged by Western blot and immunoprecipitation analyses. A protocol was developed to accurately quantitate introduced GUS in the presence of SB-GUS, by utilizing selective inhibition of GUS at pH 7.0 by saccharic acid 1,4-lactone. Under these conditions GUS activity is completely eliminated, while SB-GUS activity was unaffected.

WOZNIAK, C. A. and L. D. OWENS. 1994. Native  $\beta$ -glucuronidase activity in sugarbeet (*Beta vulgaris* L.). *Physiologia Plantarum* (in press).

$\beta$ -Glucuronidase activity, initially thought absent from plants, has been found in a variety of plant families. During an analysis of *Agrobacterium*-mediated transformation of sugarbeet (*Beta vulgaris* L.), significant glucuronidase activity was observed in control (non-transformed) tissues when the fluorogenic substrates 4-methylumbelliferyl- $\beta$ -D-glucuronic acid, resorufin glucuronic acid and 3-carboxyumbelliferyl- $\beta$ -D-glucuronic acid were used to quantify beta-glucuronidase activity under standard protocol conditions. Similarly, the colorigenic substrate p-nitrophenyl-beta-D-glucuronide was hydrolyzed by this sugarbeet-derived glucuronidase. Biochemical and immunological data are presented to indicate significant differences between sugarbeet-derived glucuronidase and that of microbial origin (i.e., encoded by *gus A*; E.C. 3.2.1.31). These differences provide a means of distinguishing the two activities in extracts that contain a mixture of both. Use of X-gluc, the substrate utilized in histochemical localizations of glucuronidase activity, gave no positive reaction products (i.e., indigo precipitate) at pH 7.0. However, at pH 3.0, 4.0 and 5.0, formation of the indigo precipitate was evident within 1 h at 37°C in sugarbeet callus and by 4 h in leaves and petioles. The specific activity of SB-GUS was observed to be strongly pH dependent, with an optimum near pH 4.0. The use of  $\beta$ -glucuronidase techniques as applied to transformation of sugarbeet is discussed.

WOZNIAK, C. A., G. A. SMITH, and L. G. CAMPBELL. 1993. Entomopathogenic nematodes for control of larvae and adults of the sugarbeet root maggot (Diptera: Otitidae). *Proc., Beltsville Symposium Biologically Based Technologies of Pest Control*, p. 40.

Entomopathogenic nematodes were evaluated for their ability to infect and reproduce within third instar sugarbeet root maggots (SBRM). Six strains of *Steinernema* representing three species and four strains of *Heterorhabditis bacteriophora* were all capable of infecting and reproducing within third instar SBRM in vitro. Incubation of nematodes at field rates of three billion/acre for

72 h at 24 C resulted in infection and subsequent reproduction of infective juveniles (IJs) within SBRM cadavers. Egress of IJs was observed at 14-21 days post-incubation. Field testing of the six steinernematids indicated that all were capable of infecting SBRM larvae under a typical sugarbeet cropping system. Nematodes were observed to remain viable in soil, as measured by trapping with *Galleria* larvae, for at least two months following application. Adult flies were also found to be susceptible to all six steinernematids tested. *S. glaseri* was found capable of infecting adult SBRM with as little as 2 h coincubation over filter paper containing IJs. Egress of nematodes was observed at 5-6 days post-incubation. Following challenge of diapaused third instar SBRM with steinernematids, pupae were observed to form at an enhanced rate relative to controls. Emerging imagos were found to consist of 25% aberrant individuals. Aberrants had vestigial or absent wings, reduced sclerotization, poor body segmentation, misshapened head capsules and unretracted ptilina. No evidence of nematode infection was observed with these aberrants. They failed to produce eggs when mated to normal flies.

WOZNIAK, C. A., G. A. SMITH, D. T. KAPLAN, W. J. SCHROEDER, and L. G. CAMPBELL. 1993. Mortality and Aberrant Development of the Sugarbeet Root Maggot (Diptera:Otitidae) After Exposure to Steinernematid Nematodes. *Biological Control* 3:221-225.

Third instar larvae of the sugarbeet root maggot (*Tetanops myopaeformis* von Röder) were challenged *in vitro* with three strains of *Steinernema carpocapsae* (Weiser), two strains of *S. feltiae* (Filipjev), and one strain of *S. glaseri* (Steiner). Three larvae were incubated in each well of a polystyrene dish containing 5 g of autoclaved coarse sand with 500  $\mu$ l of normal saline containing 270 infective juveniles. Larvae and nematodes were co-incubated at 24°C for 72 h in the dark. Larvae were then rinsed with distilled water and transferred to plaster mounts for observation. Infectivity readings were taken at 14 and 21 days post-challenge. *Steinernema carpocapsae* 'SCANMASK' showed the lowest level of infectivity, followed in ascending order by *S. carpocapsae* 'ALL', *S. carpocapsae* '252', *S. glaseri* '326', *S. feltiae* 'SN', and *S. feltiae* 'UK'. In several of the nematode challenges of diapaused larvae, resulting pupae gave rise to adult flies with gross abnormalities. Microscopic examination of these pupae gave no indication of nematode infection or an ensuing septicemia. Overall, 24.4% of the imagos arising from nematode-challenged larvae gave rise to aberrant adults. We have attributed these aberrant adults to an accelerated metamorphosis. These aberrant flies did not produce eggs, although mating attempts were observed.

# CERCOSPORA LEAF SPOT AND BIOPESTICIDE RESEARCH

G. A. Smith and J. D. Eide

*BSDF Projects 600 and 601*

**Development of *Cercospora* Resistant Breeding Lines.** Twenty breeding lines were evaluated at the ARS Fort Collins nursery in 1993. These again included several advanced multigerm leaf spot resistant lines intended for eventual release. The lines of most interest were equal to the resistant check. The 1993 leaf spot epidemic at Fort Collins was not considered reliable, thus these lines will be retested in the 1994 nursery.

**Examination and Purification of Chitinase in *Cercospora* Leaf Spot Resistant Germplasm.** Sugarbeets synthesize the pathogenesis related (PR) protein chitinase in response to fungal attack. This enzyme degrades the chitin found in fungal hyphae. We have previously shown that chitinase is expressed at higher levels in resistant lines than susceptible lines (see 1992 Sugarbeet Research Report). We are now purifying leaf chitinase proteins by homogenization, centrifugation, heat treatment, and ammonium sulfate fractionation. The activity in the ammonium sulfate fraction was 15.5 units. Protein concentrations were reduced from 235 mg to 17.45 mg. Electrophoresis of the fractions yielded enrichment of proteins with an apparent molecular weight of 26 to 30 kD. Additional purification by Q Sepharose FF chromatography separated the acidic from the basic and neutral proteins. Further affinity, PBE 94 and Mono P HR will be necessary to purify the chitinases to homogeneity before antibody production can begin. Antibody preparation can be used as a tool for detection of elevated chitinase levels in the plant using ELISA techniques. A simple antibody ELISA test can then be used to screen seedlings for high chitinase levels.

**Vectors for Delivery of Biological Control Agents for the Sugarbeet Root Maggot.** We are looking for a suitable vector for delivery of a gene or gene product active against the sugarbeet root maggot. A suitable vector for delivery of a biocontrol agent must be able to colonize the roots, be nonpathogenic, and be neutral or growth promoting. We have identified thirteen rhizobacteria from hundreds in our collection that are antifungal to *Aphanomyces cochliodes*, *Botrytis cinerea*, *Cercospora beticola*, *Phoma betae*, *Pythium ultimum* and *Rhizoctonia solani*. These bacteria were tested for effect on sugarbeet seedling growth. Treatments consisted of drenching the sugarbeet seedlings seven days after planting with  $1 \times 10^{10}$  bacteria per ml or vacuum infiltration of seed with 1% sodium alginate solution containing  $1 \times 10^{10}$  bacteria per ml. Plants were greenhouse grown and harvested one month after planting.

**Results.** *Enterobacter* treatments had the greatest fresh weight but were not significantly different from the control. The treatment with *Klebsiella* produced the only plants with significantly lower fresh weights (Fig. 1). Plants from the seed treatment had significantly lower fresh weights than the drenched seedlings (Fig. 2). We are presently testing the viability and longevity of the bacteria on the vacuum infiltrated seed.

Seeds vacuum infiltrated with antifungal rhizobacteria were tested for protection of seedlings in *Rhizoctonia*-infested soil. Vanderhave hybrid 66156 seeds were vacuum infiltrated with  $1 \times 10^{10}$  bacteria per ml in 1% sodium alginate for 1 h. The slurry was agglutinated with 0.1 M calcium chloride and allowed to dry in a fume hood overnight. Soil mix was infested with 100 CFU of *Rhizoctonia solani* AG-4 or 59-2. The experimental design was a split plot with 5 replications and 14 treatments. The subplots consisted of soil mix treated with *Rhizoctonia* AG-4, 59-2 or untreated mix. Five seeds were planted in 3-inch square pots containing the soil mix. The experiment was conducted in the greenhouse. Stand counts were taken at three weeks. The treatments

were: 1 = *Flavimonas oryzae*, 2 = *Pseudomonas fluorescens*, 3 = *Enterobacter taylorae*, 4 = *Enterobacter agglomerans*, 5 = unknown, 6 = *Pseudomonas fluorescens* a, 7 = *Pseudomonas aurantiaca*, 8 = *Serratia liquefaciens*, 9 = *Pseudomonas aurantiaca*, 10 = control (no bacteria), 11 = *Klebsiella terrigena*, 12 = *Serratia liquefaciens*, 13 = *Serratia liquefaciens*, 14 = *Pseudomonas fluorescens*.

Seedlings treated with *Pseudomonas* (treatment 14) and *Serratia* (treatment 13) gave the greatest protection to seedlings though not significantly different than the control (treatment 10) (Fig. 3). *Flavimonas* (treatment 1) provided a significantly lower level of protection than nine other treatments including the control. The use of these naturally occurring antifungal bacteria may help control seedling diseases and be a suitable gene vector against the sugarbeet root maggot. We are continuing to look at different rhizobacteria, delivery conditions and other seedling-associated microbes and their effects on sugarbeet seedling growth.

**Figure 1** The mean fresh weights of 4-week-old sugarbeet plants treated with different antifungal rhizobacteria. Bars with the same letters are not significantly different according to Duncan's multiple range test ( $P=0.05$ ).

**Figure 2** The mean fresh weight of 4-week-old sugarbeet plants treated with antifungal rhizobacteria by vacuum infiltration of seed or by drenched seedlings seven days after planting.

## Transformation of Sugarbeet by Agrobacteria.

Agrobacteria-mediated transformation is one method for delivery of a bio-pesticide gene product to the sugarbeet chromosome. Sugarbeet-associated *Agrobacterium* and type strains were tested for virulence on sugarbeet, sunflower and tobacco. Strain A281 formed the largest galls on sugarbeets. Total DNA from *Agrobacterium* were tested for the presence of the *virG* using polymerase chain reaction (PCR). None of the sugarbeet-associated *Agrobacterium* contained the 540 base pair fragment associated with the presence of *virG*. Bacteria not containing *virG*

were eliminated from our sugarbeet transformation program. We are continuing to look for highly virulent *Agrobacteria* for use in our transformation program.

**Biological Control of Sugarbeet Root Maggot.** A biological control method is being formulated to control the sugarbeet root maggot (SBRM) (*Tetanops myopaeformis*). As yet another leg of this program, we are examining the entomopathogenic fungi *Beauveria bassiana* as a control agent. The benefit of this sporulating fungi is that primary infected maggots would amplify inoculum and be available to infect other maggots.

Third instar sugarbeet root maggots were inoculated with  $3 \times 10^4$  or  $2.3 \times 10^7$  *B. bassiana* spores or conidia per ml of buffer. Mortality ranged from 5.4 to 23.6% after seven days and to a high of 54.5% after 29 days (Fig. 4). The *B. bassiana* was isolated from the infected third instar maggots and used to reinfect maggots. This satisfied Koch's postulates. We are presently testing *B. bassiana* and *Metarhizium anisopliae* on the first instar SBRM. We have obtained infection with both *B. bassiana* and *M. anisopliae* in eight days. We are presently isolating, purifying and

**Figure 3** Sugarbeet stands three weeks after planting in soil mix with 100 CFU of *Rhizoctonia solani* AG-4 or 59-2. The seed had been treated with bacteria previously identified as antifungal.

**Figure 4** Mortality of third instar sugarbeet root maggots inoculated with *Beauveria bassiana*.

identifying these isolates and attempting to reinfect first instar larvae to satisfy Koch's postulates. We also plan to test infectivity on adult flies. These fungal pathogens may complement our nematode and/or *Bacillus thuringiensis* biocontrol methods, with the added caveat of infecting first and/or second instar larvae. *B. bassiana* will be tested at two field locations in the summer of 1994.

## UTILIZING HOST RESISTANCE MECHANISMS AGAINST *RHIZOCTONIA SOLANI*

W. M. Bugbee

*BSDF Project 610*

Germplasm lines of sugarbeet (*Beta vulgaris* L.) with resistance to *Rhizoctonia solani* Kühn (teleomorph = *Thanatephorus cucumeris* (Frank) Donk) have been developed and are being used by private breeders as sources of root rot resistance for proprietary cultivars. Efforts to gain higher levels of resistance might be possible if we had a better understanding of the interaction between *R. solani* and sugarbeet. One component of the association is the variable aggressiveness among anastomosis groups (AG) of *R. solani* isolates. Seedling disease is caused by members of both (AG) 2-2 and 4 but, in general, isolates of AG 4 are much less aggressive than AG 2-2 on older plants. Factors that are suspected or have been shown to affect aggressiveness of fungal pathogens are their ability to produce pectolytic enzymes, the suppression of pectolytic enzyme production by sugars, and sensitivity to phytoalexins.

The phytoalexins, betagarin and betavulgarin, are produced in sugarbeet in response to *Cercospora beticola*. Recently, these two phytoalexins plus a third were shown to be produced by sugarbeet roots in response to infection by *R. solani*, but the authors did not report what effect the phytoalexins had on *R. solani*. Therefore, the role of sugarbeet phytoalexins in the aggressiveness of the fungus as a sugarbeet pathogen is unknown.

We reported that an AG 2-2 strain of *R. solani*, pathogenic on sugarbeet, produces pectin lyase (PNL) and exopolysaccharuronase (exoPG) in culture and in rotted tissue. PNL was associated more with diseased roots than exoPG. We proposed that a constitutive, cell wall bound, pectin lyase inhibitor protein (PNLIP) is part of the sugarbeet's root rot resistance mechanism. To what extent the aggressiveness among isolates of *R. solani* is affected by PNLIP also is unknown.

To gain a better understanding of factors that might influence the aggressiveness of *R. solani* toward sugarbeet, isolates of AG 2-2 and AG 4 from wide geographic areas were examined for their sensitivity to phytoalexins, production of PNL and exoPG, sugar suppressiveness of pectinase production, and their susceptibility to PNLIP.

*Discussion of Results.* Sugar suppression of PNL production and the ability of the fungus to produce PNL appear to be more important root rot factors than the sensitivity to PNLIP or

accumulated phytoalexins. Although the two most aggressive isolates of AG 2-2 were more tolerant to phytoalexin than the less aggressive isolates, the response was not consistent because two isolates of AG 4 that did not cause disease were just as tolerant to phytoalexins. Therefore, sensitivity to phytoalexins was not consistently associated with root rot when considering both AGs. The limited role of phytoalexins in disease resistance is recognized. Some of these limitations evidently exist in this *Rhizoctonia*-sugar beet association. If phytoalexin production by infected sugar beets has a major role in biochemical resistance, the effect was not sufficient to account for the inability of the AG 4 isolates to cause disease on older roots.

The absence of root rot consistently was associated with an isolate's inability to produce sufficient amounts of PNL and its susceptibility to sugar suppression of PNL production. Two isolates of AG 2-2 had low aggressiveness, and three of the four isolates of AG 4 were not able to cause root rot. These isolates produced significantly less PNL and their PNL production was suppressed further by sugars compared with the more aggressive isolates of AG 2-2. Altered aggressiveness caused by sugar suppression of pectolytic enzyme production has been reported before. Others have shown that glucose, fructose, sucrose and other sugars decreased the aggressiveness of *R. solani* on cotton seedlings through suppression of pectolytic enzyme production. The aggressiveness of *Fusarium oxysporum* f. sp. *cepae* on onion was related to the suppression of PNL by sugars that had accumulated in tissues. Mean sucrose content of roots assayed in this study was 7% by weight (69  $\mu\text{g}/\text{mg}$ ) and would reach 16 to 18% under normal field conditions, while sugars in petioles were only 0.1 to 2%. The sucrose level in roots would be sufficient to suppress PNL production by *R. solani*. The aggressiveness of AG 4 isolates on seedlings, but not on older plants, may be related to the content of sugars in young plants. The sugar content in seedlings might not be enough to suppress pectolytic enzyme production so the fungus is able to cause disease. Therefore, efforts to enhance early sucrose accumulation in seedlings might improve resistance to *R. solani*.

The effectiveness of PNLIP was not associated with differential aggressiveness among the isolates tested here. When the ratio of PNLIP to PNL was high enough, complete inhibition of PNL occurred. For this reason, the inhibition of PNL activity, and hence aggressiveness of *R. solani* might be correlated with the PNLIP content in cell walls. Therefore, manipulation of the gene that encodes PNLIP and the transformation of sugarbeet to overproduce PNLIP should enhance the host's resistance by suppressing the activity of PNL. Reduction of PNL activity by elevated PNLIP levels would complement the sugar-suppression of PNL production that apparently already exists in sugarbeet roots.

**Manipulation of a Root Rot Resistance Factor.** The strategy is to identify an important biochemical mechanism of pathogenesis in the pathogen and then to identify complementary resistance mechanisms in the sugarbeet. If resistance factors can be easily detected, or easily manipulated at the molecular level, then sugarbeets with high levels of the factor could be identified in the greenhouse or created in the laboratory. This approach complements the current, labor-intensive, field method of developing *Rhizoctonia*-resistant germplasm. A positive correlation of high levels of a known resistance factor with root rot resistance would provide the impetus for a novel, more efficient breeding program.

**Results.** We have shown that the aggressiveness of *R. solani* toward sugarbeet is due largely to the amount of PNL that is produced by the fungus. PNL is a cell-destroying enzyme. The sugarbeet produces PNLIP as part of its resistance arsenal. Plants with high levels of PNLIP might also have elevated root rot resistance. We have used polyclonal and monoclonal antibodies against purified PNLIP in a double antibody sandwich enzyme-linked immunoassay (DAS-ELISA) to detect PNLIP in sugar beet extract. Out of < 1600 greenhouse-grown, three-month-old plants that were assayed, several individuals with high PNLIP values were selected and induced to flower. Tissue cultures were initiated from axillary buds of the selections to produce clones. The selected plants are from: 1) F1001, a germplasm line with resistance to *Phoma betae*, a storage rot pathogen that was selected from a Russian introduction; 2) F1010, a high sucrose germplasm line from an interpollinated population of individuals from the world collection; 3) 75B7, a germplasm line with resistance to *Botrytis cinerea* that was developed from another Russian introduction; and 4) 768, a germplasm line with resistance to *P. betae* also selected from a Russian introduction. The intent is to cross these clones to generate synthetic lines and then to evaluate them for resistance to *R. solani*.

**Toward Cloning and Sequencing a Root Rot Resistance Gene.** The objective here is to clone the sugarbeet gene that is responsible for the production of PNLIP and then to manipulate this gene to overproduce the PNLIP under the assumption that plants with very high levels of PNLIP will be more resistant to *Rhizoctonia* root rot.

mRNA was purified from sugarbeet leaf tissue and used to produce cDNA. A cDNA library was generated in *Escherichia coli* using the plasmid pcDNAII (Invitrogen Corp.) as the vector. The library was probed with an antibody to PNLIP but no clones producing PNLIP were detected. A second library was produced using mRNA from sugarbeet root. Several transformed colonies of *E. coli* were positive when lysates were probed with a polyclonal antibody. These clones are being evaluated for synthesis of PNLIP.

## BROADENING THE GENETIC BASE OF SUGARBEET (Pre-breeding)

D. L. Doney

*BSDF Project 630*

Continued sugarbeet improvement is dependent on the availability of desirable genetic variation. The genetic background from which most present day sugarbeet cultivars originated is considered by most sugarbeet breeders to be narrower than that for other cross-pollinated crops. There appears to be sufficient genetic variability for cultivar improvement in the short term; however, long term improvements may be impeded if significant infusions of new and/or additional genetic variability are not made.

The primary objective of this research is to develop near-sugarbeet type populations containing new genetic variability for use in elite sugarbeet breeding pools. Secondary objectives include

the development of selection criteria that are effective in creating near-sugarbeet type populations.

**Near-sugarbeet Selections.** Individual family lines derived from a cross between sugarbeet inbred L53 and wild beet accession PI 546420 were tested for combining ability in 1993. L53 is a self-fertile, O type, multigerm inbred with high general combining ability for root yield. PI 546420, *Beta vulgaris* subspecies *maritima*, was collected near Thessaloniki, Greece by C. Goulas in 1978. It is multigerm, annual and prostrate in growth habit.

These family lines resulted from four cycles of mass selection for root shape. By the third cycle, roots were beginning to look like sugarbeet roots. For each cycle, all selected plants were randomly intercrossed in open-pollinated isolation cages and, except for cycle four, harvested in bulk. In cycle four, seed was harvested from each plant and maintained as individual family lines. Annuals were eliminated in the early cycles. Family lines from cycle four were crossed to sugarbeet inbred L33cms for combining ability analyses. The resulting crosses along with the respective family lines were tested in replicated field trials in 1993 (Tables 1 and 2).

**Table 1.** Root yield, sucrose percentage and sugar yield for eight family lines and their respective test cross and the mean of two commercial hybrid checks.

Family line	Root yield		Sucrose		Sugar yield	
	Line	Test cross	Line	Test cross	Line	Test cross
	T/A	T/A	%	%	LB/A	LB/A
x115-1	8.0	16.3**	14.1	14.1	2241	4934**
x115-4	14.9	16.0	13.0	13.8	3892	4403
x115-6	10.8	15.2**	14.8	14.9	3190	4527**
x115-7	10.2	19.7**	14.8	14.7	3045	5798**
x115-9	11.9	16.1**	13.0	13.9*	3299	4427**
x115-10	16.6	17.6	13.0	14.2*	4291	5419**
x115-11	13.2	17.9**	12.9	13.6	3407	4853**
x115-13	15.3	22.3**	12.3	13.5*	4069	5963**
Commercial Hybrids		20.5		15.0		6170
LSD 0.05		3.3		0.9		688

\*, \*\* = Test cross significantly greater than the family line at  $P = 0.05$  and  $P = 0.01$ , respectively.

**Table 2.** Root yield, sucrose percentage and sugar yield for seven family lines and their respective test crosses and the mean of two commercial hybrid checks.

Family line	Root yield		Sucrose		Sugar yield	
	Line	Test cross	Line	Test cross	Line	Test cross
	T/A	T/A	%	%	LB/A	LB/A
x115-14	7.7	16.3**	13.5	14.1	2076	4598**
x115-18	15.6	17.7	14.3	14.4	4466	5088
x115-19	10.9	17.4**	13.7	14.2	2921	4918**
x115-20	9.5	16.6**	12.9	13.7*	2451	4537**
x115-22	8.4	18.6**	13.9	14.0	2322	5200**
x115-26	11.8	18.2**	12.3	13.6*	2815	4956**
x115-28	12.5	19.8**	13.0	14.0*	3245	5550**
Commercial Hybrid		19.9		15.1		6036
LSD 0.05	2.7			0.8		
763						

\*, \*\* = Test cross significantly greater than the family line at  $P = 0.05$  and  $P = 0.01$ , respectively.

All but three of the family lines tested showed significant heterosis for root yield and sucrose yield (test cross vs. family line). Only those with low sucrose percentages showed a significant increase in sucrose percentage in the test cross. Several of the test crosses are approaching the commercial hybrids in root and sucrose yield (Tables 1 and 2). There were no differences in sodium, potassium and amino nitrogen between the test cross and parent line nor between the family lines and the hybrid checks (data not shown). All but two of the family lines had tare ratings very similar to the hybrid checks, suggesting that the root types were very similar to sugarbeet and generally void of sprangling. Several of these lines will be released to the industry for use in elite breeding pools.

**New Populations.** New populations derived from crosses between a sugarbeet line segregating for genetic male sterility and regional mixtures of *Beta maritima* or other subspecies of *B. vulgaris* are in the developmental stage. Except for the elimination of annuals, selection was not practiced in the first two cycles of random intercrossing. In the first two cycles, seed was harvested from male sterile plants to insure recombination of the two sources of germplasm (sugarbeet and wild types).

Following the two cycles of random intercrossing, two cycles of selection for early germination and fast leaf initiation have been conducted. Slow germination and slow leaf initiation have been observed by the author in many of these wild populations. Growth chamber selection procedures developed by this lab have proven effective in eliminating germination inhibitors and increasing leaf initiation. Both traits are highly heritable and can be selected against when conditions are properly controlled. The effects of one cycle of selection for early germination and early leaf growth are given in Tables 3 and 4, respectively.

---

\* = Source of wild germplasm in the initial cross.

---

In every cross there was a significant decrease in hours from planting to emergence for the first cycle of selection (Table 3). Hours from planting to emergence were very similar for each first cycle selection population, suggesting that most germination inhibitors had been eliminated in the first cycle.

There were significant differences in the growth rate of the first leaf of the parent populations (Table 4). The slowest were those with the North Atlantic as the source of wild germplasm. A significant increase in growth rate of the first leaf was observed after the first cycle of selection for all populations. These data suggest that the selection procedure was very effective. The parent and selection populations will be grown in the field in 1994.

**Green Leaf Duration.** Studies over the past three years (see Sugarbeet Research Reports 1991 and 1992) have found that: 1) the green leaf duration of the first leaf can be altered genetically, 2) selections for the green leaf duration of the first leaf affect the green leaf duration of other leaves as well as the leaf canopy in general, and 3) selection for early green leaf duration increased the frequency of annuals in populations segregating for annualism.

Subsequent studies have focused on strong biennial populations. Two cycles of mass selection for divergent green leaf duration have been completed in one broad genetic base population (i32) and one relatively narrow genetic base population (3747). These new populations along with their respective parent populations were evaluated in replicated field trials in 1993 (Tables 5 and 6).

---

LSD 0.05		2.9	1.0	628

\* = Values followed by the same letter are not significantly different at  $P = 0.05$ .

Unfortunately, heavy rains in June and July flooded these yield trials, resulting in very low yields. However, the relative rank of other flooded trials did not change even though the root yields were reduced dramatically. Earlier pilot tests suggested that increasing green leaf duration increased root yield. The first cycle of selection substantiated these earlier data, especially in the i32 population (Table 5). Selection for increased green leaf duration (population x127 L) significantly outyielded the parent population for sugar yield and root yield. The divergent selection, i.e. for decreased green leaf duration (population x129 E), gave significantly lower sugar and root yields than the parent population. Divergent selection in the more genetically uniform population (3747) gave the same but not significant trends, i.e. increased green leaf duration increased yields and decreased green leaf duration decreased yields (Table 6).

The second cycle of divergent selection in each population did not have the same effect on yield (Tables 5 and 6). An additional cycle of selection for early green leaf duration, populations y218 EE and y215 EE, gave yields similar to the first cycle for early green leaf duration. The additional cycle of selection for increased green leaf duration, populations y216 LL and y214 LL, were lower in yield than the first cycle for increased green leaf duration.

The results of the second cycle of selection may reflect some apparent inbreeding depression in the second cycle. However, population numbers were between 30 and 50 selected roots and that number of roots in such a diverse population as i32 should not show significant inbreeding. It may also be suggested that the first selection cycle captured most of the additive genetic variation for this trait. Studies are underway to identify and evaluate the importance of non-additive gene action for this trait.

**Leaf Initiation.** Carefully controlled growth chamber selection techniques have shown that leaf initiation can be altered genetically. Preliminary evaluation tests in 1992 were inconclusive. This past year field trials were conducted to evaluate the effects of both mass selection and combining ability selection for leaf initiation on yield. These trials also experienced flooding which resulted in reduced yields.

Leaf initiation was measured at three-hour intervals. Those that initiated first (one SD above the mean) were intercrossed to produce the Fast Leaf Initiation population. Those that were the last to initiate leaves (one SD below the mean) were intercrossed to produce the Slow Leaf Initiation population. There was a significant difference in root and sugar yield between the fast and slow leaf initiation population (Table 7). The parent population was between the fast and slow leaf initiation populations but not always significantly different. Sucrose concentration was not affected by selection for leaf initiation.

---

**TABLE 7.** Effect of mass selection for leaf initiation on root yield sucrose percentage and sugar yield.

---

\* = values followed by the same letter are not significantly different at  $P = 0.05$ .

---

Recurrent selection for leaf initiation combining ability was accomplished by test crossing each plant from a broad genetic base population to the L53cms inbred. As soon as crossing was complete, the male parent was trimmed and placed in a thermal induction chamber until the evaluation of all the test cross progeny was complete. Test cross progeny were evaluated for leaf initiation in controlled growth chambers. Male plants whose test cross progeny gave the fastest leaf initiation were intercrossed to produce a new Fast Leaf Initiation population, and those plants whose test cross progeny gave the slowest leaf initiation were intercrossed to produce a new Slow Leaf initiation population (Table 8). These new populations, their respective test crosses and the parent were tested in a replicated field trial in 1993.

Recurrent selection for fast leaf initiation resulted in significantly higher root and sugar yields as compared to recurrent selection for slow leaf initiation. The parent population yield was

**TABLE 8.** Effect of recurrent selection for leaf initiation on root yield, sucrose and sugar yield.

	<u>Root yield</u>		<u>Sucrose</u>		<u>Sugar yield</u>	
	Popu- lation	Test cross	Popu- lation	Test cross	Popu- lation	Test cross
	T/A	T/A	%	%	Lbs/A	Lbs/A
Fast Leaf Initiation	10.0	12.9*	13.1	13.7	2644	3540**
Slow Leaf Initiation	7.6	9.8	12.2	13.5*	1912	2550**
Parent	9.6		12.9		2501	
LSD 0.05	2.9		0.9		719	

\* = Significant increase of test cross over population at  $P = 0.05$ .

\*\* Significant increase of test cross over population at  $P = 0.01$ .

between the new fast and new slow leaf initiation populations but not significantly different from either (Table 8).

These results suggest that both additive and non-additive gene action are operative for leaf initiation and that both indirectly influence root yield. Since these data are from a field severely affected by flooding, additional studies are underway to gain more reliable data.

## WORLD *BETA* NETWORK

D. L. Doney

*BSDF Project 631*

The Third International *Beta* Genetic Resources Workshop and World *Beta* Network Conference was held in Fargo, North Dakota, August 4-6, 1993. More than 70 scientists from 16 countries, including representatives from China, India, Japan, Poland, Egypt, Morocco, Eastern and Western Europe and the United States attended the three-day conference.

Founded in 1989, the World *Beta* Network (WBN) objective is to provide a forum for international involvement in *Beta* germplasm resources. In addition to germplasm activities such

as preservation, documentation, evaluation and utilization of germplasm, scientific sessions were held on Pre-breeding and Gene Transfer.

In the Pre-breeding session, talks covered theory, methods and the development and utilization of wild germplasm. Examples were given of the successful incorporation of foreign germplasm into useful cultivars. Other topics included pre-breeding for root architecture; male sterility; and root rot, nematode, virus yellows, and Rhizomania resistance. Two papers dealt with general aspects of pre-breeding in India and the former Soviet Union.

The Gene Transfer session concentrated on recent efforts to utilize new molecular technology to enhance sugarbeet pest protection and sugarbeet production. Topics encompassed the utilization of RFLP technology in *Beta* and the transfer of herbicide, nematode and root maggot resistance. One paper proposed a revision of the taxonomy of the genus *Beta*. This proposal, to be published in the next issue of the *Journal of Sugar Beet Research*, was considered and accepted by the conference.

A poster session of varied topics was also part of the conference. Contributions included tissue culture, isozyme characterization of wild germplasm, molecular identification of sugarbeet varieties, core collections, collecting beet in Egypt, and resistance to leaf spot, *Polymyxa*, BNYVV, and *Sclerotium* root rot.

The workshop section of the conference consisted of reports of germplasm activities from different parts of the world, proposals, and regional panel discussions and recommendations. Recommendations made by the conference were as follows:

- 1) Areas of naturally occurring *Beta* germplasm deficient in *ex situ* collection were identified. Priorities were centered in Middle Eastern countries with additional needs in several Mediterranean countries.
- 2) Recommended seed multiplication of selected germplasm for evaluation purposes. Several private companies, gene banks and government agencies agreed to participate in the seed increase program.
- 3) Evaluation for specific priority descriptors was identified as a major need. Several companies, gene banks and government agencies agreed to conduct evaluations based on their respective capabilities.
- 4) The proposed revision of the taxonomy of the genus *Beta* was discussed at length and officially accepted by the conference following an official release of the revision.
- 5) The proposal for a WBN newsletter was deemed unnecessary and shelved.
- 6) Past financing of the WBN has been obtained from the IBPGR and private industry. Future funding from both sources is unlikely. Recommendations were made to increase registration to cover conference costs and to petition international institutions to support travel of participants from developing countries.

7) The next WBN conference will be held in Izmir, Turkey (1995), to coincide, either before or after, with the summer meetings of the IIRB.

Other highlights of the conference included a field demonstration of the world *Beta* germplasm, a keynote speech by Henry Shands (Associate Deputy Administrator for Genetic Resources - USDA), and tours of the American Crystal Sugar Co. research facilities and Hilleberg AB research field trials.

Conference papers will be published in a special issue of the *Journal of Sugar Beet Research*.

## BIOLOGICAL CONTROL OF SUGARBEET ROOT MAGGOT

C. A. Wozniak and Sarah E. Hinz

*BSDF Project 641*

**Insect Endogenous Bacteria and Their Influence on Sugarbeet Root Maggot Development.** Many multicellular organisms are closely associated with specific microbes and often fail to grow or develop normally in the absence of these symbionts. In most cases the role that these microbes play is unknown. We have demonstrated that the sugarbeet root maggot (SBRM), *Tetanops myopaeformis*, contains a set of bacterial associates that are reproducibly isolated from larvae originating in separate, distinct locations.

Our analyses of insect endogenous bacteria (IEB) associated with SBRM third instar larvae has led to the isolation and characterization of over 1000 bacteria from five states. Although some species are regularly found associated with SBRM (*i.e.*, *Serratia liquefaciens*, *S. marcescens*, *Flavobacterium indologenes*, *F. gleum*), they may be absent depending on geographic origin. We have found only one species, *Stenotrophomonas maltophilia* (formerly *Xanthomonas maltophilia*), to be ubiquitously encountered in SBRM larvae.

This finding implies some role for *S. maltophilia* (Sm) in the biology of SBRM. We have evaluated larvae reared in the absence of microbes (gnotobiotic) produced via surface disinfestation of SBRM eggs. Attempts to rear these gnotobiotic larvae in culture with sugarbeet suspension culture cells or seedling roots have proved unsuccessful. Growth and morphogenetic development (*e.g.*, moulting) failed to occur despite larval survival for time periods sufficient for development under field conditions.

**Assessment of IEB in SBRM Development.** To determine the potential of these IEB in SBRM development, gnotobiotic SBRM first instars were cultured with suspension culture cells on gelled medium with and without additions of individual bacterial isolates.

Surface disinfestation of laboratory-reared SBRM eggs was accomplished with detergents (*i.e.*, 1% (w/v) SDS, 0.03% (v/v) Roccal) and sodium hypochlorite (0.2% (v/v)). Lack of aerobic, heterotrophic organisms on nutrient media was confirmed. Gnotobiotic eggs placed on this

Murashige and Skoog Minimal Organics Medium (pH 5.7) with 3% (w/v) sucrose (MS0) hatched within 5 days at 24°C. Two days after egg placement, *Beta vulgaris* 'REL-1' suspension cultured cells (2.0 ml) were added to each 35-ml plate of MS0. Broth cultures of *Pseudomonas syringae* 'aptata' (from lesions on sugarbeet leaves), *Serratia liquefaciens* ATCC 27592, *Escherichia coli* 'JM109' and '2P16A' (from third instar SBRM) were quantified by absorbance measurements at 595 nm and dilution plating. These bacterial cultures were added to MS0 plates in 100 µl broth containing  $5 \times 10^8$  to  $5 \times 10^9$  cfu. Control treatments included the absence of 'REL-1' cells, the absence of bacteria, or eggs-only with no added cells or bacteria. Attempts to rear eggs with total native IEB complement (*i.e.*, without surface disinfestation) resulted in overgrowth of MS0 plates by *Penicillium* or *Aspergillus*, thus precluding observations of SBRM growth and development.

Incubation of MS0 cultures at 24°C (16/8 h photoperiod in diffuse fluorescent lighting) resulted in establishment of the added bacteria in feeding tunnels of the larvae and on 'REL-1' cells. The low available organics and acidic pH minimized spread of bacteria across the medium surface, which prevented sugarbeet cells and larvae from being overgrown with bacteria which could have proved toxic due to production of waste products. Culture samples taken at the end of experiments (approximately 6 weeks) demonstrated the survival of strains added at the onset of egg hatch.

SBRM first instars incubated in the presence of *S. maltophilia* '2P16A' (or type strain ATCC 13637) moulted within 10 days. A concomitant increase in size and change in morphology (*e.g.*, sclerotization of caudal spiracles, development of secondary pharyngeal supports) also was observed. This development (moulting) was within the expected time frame for SBRM of 7 to 12 days based on field observations. Feeding of larvae was observed in all treatments with suspension culture cells regardless of bacterial addition. Utilization of sugarbeet cells and associated calli was observed by a decrease in tissue mass with time and a browning of calli; bacterial influence on tissue browning was not separable from effects of larval feeding.

Co-cultures of 'REL-1' cells and *Ps. syringae* 'aptata', an opportunistic sugarbeet leaf pathogen, resulted in clumping of bacteria and sugarbeet cells into strand-like formations. However, this isolate was capable of providing for moulting and growth of SBRM larvae in the presence of 'REL-1' cells. No development was observed without cells in the presence of bacteria. Greenhouse evaluations of this organism demonstrated capacity for induction of a hypersensitive response (HR; browning, cell collapse) on tobacco and watersoaked lesions or chlorosis on *Beta vulgaris* B1745 and H5135. Hence, the response of suspension cells to *Ps. syringae* contact was not totally unexpected and may be a form of HR or disease etiology.

SBRM development proceeded in the presence of 'REL-1' cells and *E. coli* 'JM109'. It was apparent that these bacteria were influencing suspension culture cell multiplication and were proliferating at different rates than other bacteria on MS0 medium. Hence, direct comparisons are difficult, especially in these preliminary experiments.

*S. liquefaciens* ATCC 27592, although capable of inducing moulting in one instance, had an apparent negative influence on SBRM and 'REL-1' cells. This strain proliferated on MS0 and many deceased larvae were observed. The inherent variation in bacterial species and strains to

utilize different substrates as nutrient sources may in part explain the unusual growth of this organism on what would be considered a "minimal medium". In addition, sequestration of particular ions (*e.g.*, iron) by siderophores and antibiosis through secondary metabolite production are known to be responsible for competitive or allelopathic interactions.

The ability of various bacterial species to mediate the interaction between SBRM larvae and sugarbeet cells suggests a common factor(s) shared by many prokaryotes. Such commonality has been demonstrated in rearing of Muscidae (house flies) *in vitro*. Several unrelated gram negative bacteria were found capable of supplying gnotobiotic maggots with sufficient factor(s) to provide for larval development, however, their capacities to do so varied with individual species (Martin *et al.*, unpublished data). In contrast, many species of *Bacillus* (gram positive) were found to have inhibitory influence on house fly morphogenesis.

Due to the omnipresence of Sm on sugarbeet roots and within SBRM larvae, this species appears to be the most promising candidate for vectoring a toxic protein (*e.g.*, Bt-ICP, protease inhibitor) to the feeding court of this insect. Our evaluations on plant pathogenic potential of multiple Sm strains indicated that this species is not a plant pathogen. Experiments designed to assess the ability of culture filtrates of Sm to mediate the SBRM feeding interaction with sugarbeet tissue are underway. Fractionation of any active components could yield significant knowledge of the critical interplay of SBRM larvae and microbes. Engineering of Sm with foreign DNA at the chromosomal level could provide a specific, stable biopesticide applicable to sugarbeet hybrids via seed or soil inoculation. Our ongoing studies of microbial influence on SBRM will allow assessment of the sugarbeet rhizosphere with respect to scarring and for identification of a microbial vector for interruption of the SBRM life cycle.

**Isolation and Characterization of *Bacillus thuringiensis* for Biocontrol of Sugarbeet Insect Pests.** The naturally occurring soil bacterium *Bacillus thuringiensis* (Bt) is the most widely used biological pesticide worldwide and currently comprises approximately 2% of the total pesticide market. The ability to obtain isolates from numerous environmental sources without concern over patent or ownership rights has allowed significant commercial input in the development of new product formulations. Strains with biocidal activity towards many key insect orders and a few other invertebrate phyla have provided the target specificity and genetic variability needed to direct products towards specific markets.

Isolates with activity against Diptera (*e.g.*, blackflies, mosquitoes) are known. However, isolates with activity against the sugarbeet root maggot (SBRM; Diptera:Otitidae) or most other insect pests of sugarbeet have not been suitably evaluated. The two primary goals of this project were 1) to isolate, characterize and screen new Bt strains, and 2) to clone the responsible *cry* or *cyt* gene from Bt to a suitable rhizospheric bacterial vector (see Project 601 report).

**Isolation of Bt.** Established methods of Bt isolation were modified and combined to provide for isolation of Bt from a variety of samples. Soil, insects, plant debris and plant roots were sampled by suspending extracts in 0.85% saline and pelleting debris at low centrifugal force. The supernatants from these extractions were adjusted to 0.25 M with sodium acetate and incubated overnight at 30°C, 200 rpm. Under these conditions most microbes initiate growth and division with the exception of Bt endospores. Cultures were subsequently heat treated

(80°C, 10 min) and plated onto rich media with ampicillin (100 µg/ml) and Polymyxin B (40 µg/ml). After incubation for 24 to 48 h colonies resembling *Bacillus* spp. were subcultured to Bt/Amp/PolB for isolation. Isolates were gram stained, stained with Malachite green/Safranin O to check for crystal/spore production and biochemically characterized using the Biolog 3N database.

All environmental samples collected (soils from root zones, ant hills, horse barns, pastures and river banks) were positive for the presence of Bt. Forty-five isolates were obtained from these samples and were analyzed biochemically and genetically for differentiation into one of the five recognized Bt insecticidal crystal protein (ICP) subgroups. The combination of acetate selection, heat treatment and antibiotic selection during screening of samples yielded Bt strains with few extraneous organisms. *Bacillus* spp. identified were *B. thuringiensis* (Bt), characterized as: bacilliform, gram positive, spore forming aerobes, with crystal inclusion bodies. Although acrySTALLIFEROUS strains of Bt are known to exist, we did not encounter any in our sampling. Several additional Bt strains were identified from our sugarbeet root and insect studies and similarly characterized.

*Analysis of Bt Strains.* Isolates were grown to sporulation (*i.e.*, cell lysis) in broth, centrifuged, washed in distilled water and separated on density gradients. Pre-centrifugation preparations of spores/ICP crystals and the fractions from the density gradients were analyzed by SDS-PAGE. Type strains of Bt (from ATCC, Rockville, MD) were also analyzed for comparison.

Protein profiles on SDS-PAGE from presumptive Bt isolates were indistinguishable from crystal preparations of 'israelensis' type strains treated similarly. Peptides in the 25 - 28 kD (Cry A) range and 68 - 72 kD (Cry IV) range are predominant, with some isolates showing bands of 120 - 130 kD (presumably protoxin). Fractional analyses from NaBr density gradients, however, were hampered by irregular banding on the gradients. Diminution of density fractions in the ranges of presumptive Cry IV toxin proteins (on SDS-PAGE) suggested that some of these isolates were solubilized in NaBr during centrifugation. Solubilization of ICP during NaBr centrifugation has been attributed to Cry III toxins (*i.e.*, coleopteran active strains).

A cry IV-specific oligonucleotide primer was employed in a polymerase chain reaction (PCR) to evaluate the sequence and identity of ICP genes present in our isolates. Cry IV toxins have shown activity against numerous Dipteran insects and thus were chosen as the basis of our selection protocol. After screening over 70 isolates with cry I, cry III, and cry IV - specific primers via PCR, it was apparent that Cry IV ICP were the predominant proteins encoded in these strains. Several isolates, however, contained more than one reactive ICP sequence, as judged by PCR product size on electrophoretograms. This finding was corroborated in part by the complex plasmid profiles found in many of the strains, and by the ability of plasmid DNA preparations to serve as templates for PCR-mediated cry sequence production.

*In vitro SBRM Feeding Assay.* Latex spheres covalently bound with fluorescein (Fluospheres) were used to demonstrate uptake and ingestion by SBRM larvae of particulates within the known size ranges of Bt spores and ICP crystals. Larvae were observed to ingest and concentrate latex spheres in the size range of Bt spores and crystals, with primary concentration of these particles in the midgut region. The cibarial pharynx of larval SBRM is size selective with respect to

ingestion. Fluosphere uptake and retention in the midgut (evidenced by epifluorescence microscopy) indicated the potential of crystal/spore presentation to these insects during *in vitro* screening assays.

First instar SBRM were co-incubated with crystal/spore preparations from all novel isolates. Application of preparations to filter paper discs or in coarse sand resulted in none of the isolates being demonstrably toxic to the larvae. The lack of an *in vitro* rearing system for SBRM and the phytophagous nature of SBRM larvae preclude the addition of useful feeding adjuvants or stimulants to bioassays. The time provided for ingestion of spores and/or crystals may be insufficient in the absence of normal feeding behavior. Lack of available nutrition in assay mixtures may prevent sufficient uptake of ICP to ensure visible toxicity assessment prior to insect starvation. Investigations of lab rearing systems for culturing/bioassay techniques are underway. The finding by a colleague that one of our *cry* IV isolates has activity against a coleopteran pest of sunflower has influenced our decision to screen all isolates via bioassay and not to preclude any strains based on PCR data. The strict categorization of Cry toxin groups may not be as sound as once thought based on our findings.

## NEMATODE RESEARCH

C. A. Wozniak, G. A. Smith and L. G. Campbell

The target specificity of entomopathogenic nematodes for soil-borne insects and their low environmental impact have made them a focus of our work on biological control of the sugarbeet root maggot (SBRM). This dipteran has been a cause of significant loss to sugarbeet growers in several states as larval root feeding reduces stand and severely debilitates surviving plants.

With the advent of large-scale production techniques, several species of entomopathogenic nematodes are now available for evaluation against insect pests. These insect-specific nematodes are known to infest and reproduce within a wide range of insects, but are especially useful and effective against soil-inhabiting larvae. Application and manufacturing methodologies have progressed to the point of economic feasibility for many cropping situations wherein a large, inundative release of infective juvenile (IJ) nematodes to the subsoil profile results in pest decline. The prolific reproduction of IJ within insect cadavers provides for secondary release within the target zone of the insect pest.

Two primary nematode groups, the steinernematids and the heterorhabditids, are the current focus with respect to agricultural use. Although the reproductive biology of these two groups differs somewhat, the basic mechanism of action is the same. Bacteria of the genera *Xenorhabdus* and *Photorhabdus* are symbiotic with nematodes in the Steinernematidae and Heterorhabditidae, respectively. Upon entry into the host insect via mouth, anus or spiracles, the gut-harbored symbionts are released to the haemocoel or blood sinus of the insect. Bacterial septicemia ensues within 24 h and death is usually apparent within 24 to 48 h. IJ nematodes utilize the degradation products of bacterial action as nutrition needed for reproduction. Several thousand new IJ are released from the host cadaver following exhaustion of nutrient supply.

Larval SBRM were assessed for their susceptibility to infestation/parasitism by IJ of three steinernematid species and one heterorhabditid species in laboratory bioassays. Co-incubation of any of the six strains of *Steinernema* spp. or the four strains of *Heterorhabditis bacteriophora* resulted in infection of third instar SBRM larvae. Application of commercially produced steinernematids or lab-reared heterorhabditids to coarse sand containing SBRM for 72 h always resulted in infection of at least some of the third instars. In several experiments, however, the initial presence of IJ observed within deceased larvae failed to result in nematode reproduction and release. The lack of suitable establishment of bacterial septicemia within the host is presumed to be the cause of reproductive failure. Our parallel studies on variation in SBRM endogenous flora indicated that antagonistic microflora could limit establishment of successful septicemic conditions by *Xenorhabdus* or *Photorhabdus* spp. Although death of SBRM ensued following nematode invasion, the proper nutrient composition was lacking for IJ reproduction.

Adult SBRM (flies) were also evaluated under lab conditions for susceptibility to steinernematid IJ. Flies were incubated on moist filter paper discs containing one of six strains of *Steinernema* spp. in numbers approximating field rates (*i.e.*,  $3 \times 10^9/A$ ). Removal of flies at time points from 2 h to 36 h after introduction of IJ provided a time-course analysis of infectivity. Flies were transferred to sterile, coarse sand for observation of infection, death and IJ egress.

With as little as 2 h co-incubation, 42% of adult SBRM were observed to be infected, with death following in 12 to 24 h. Longer incubation times of 4, 6, 18, 21 and 36 h resulted in 50, 70, 75, 77 and 100% infection. Reproduction of IJ within flies was rapid relative to larval infections (3 to 5 days vs. 10 to 21 days) and presumably resulted from the rapid diminution of host nutrients in adults. Flies contain a predominance of sclerotized and chitinized structures not amenable to degradation and use as a nutrient source.

An unexpected observation resulted from *in vitro* evaluation of larval susceptibility. Third instar SBRM that had completed the mandatory diapause period (*i.e.*, cold induction) needed for pupation were often found to pupate in response to IJ exposure. This induction of puparium formation was presumed to be a defense response to nematode invasion. However, 25% of the resultant images were aberrant in morphology. The morphology of these aberrant flies included unretracted ptilina, misshapened head capsule, reduced sclerotization of the cuticle, reduced or absent wings, and a general diminutive nature. Attempts to obtain eggs from these aberrants was unsuccessful.

*Field Assessment of SBRM Susceptibility.* Six strains of *Steinernema* spp. were applied in subsoil along the length of sugarbeet rows for two consecutive seasons. Three applications of nematodes at  $3 \times 10^9$  IJ/A were used to enhance the probability of influencing SBRM larval numbers. Infected third instars were collected from all nematode treatments, however, the heavy clay soil precluded accurate assessment of % infection. Sampling of larvae was skewed towards collection of healthy (white) larvae, as infected cadavers become soft, brown and are degraded within days in the soil.

Due to the excessive, abnormal rain patterns present over much of the Red River Valley these past two seasons, timely sampling of nematode persistence was hampered. However, we did find that IJs survived from the final application (late July) until the first week of October.

Additionally, many native nematodes with evidence of insect pathogenic potential were recovered from soil samples.

Comparison of strains, controls and chemical applications in 1993 indicated that one strain of *S. carpocapsae* (252) may have some potential against SBRM larvae. Overall, however, none of the other nematode strains indicated a statistically significant ( $P = 0.05$ ) decrease in root damage ratings compared to controls. Similarly, with % sucrose, tonnage and sucrose purity, no statistically verifiable difference was noted with nematode treatments. We plan to assess heterorhabditid strains in 1994, along with novel strains of *Steinernema* previously unavailable. With more typical weather patterns for this area, we expect the experiments to reflect an accurate potential of entomopathogenic nematodes with respect to reducing SBRM numbers below critical damage levels.

Monitor stations and milk carton traps were evaluated in 1993 as infection sites for adult SBRM. Emerging flies from a previous season's beet field were captured in nonbaited monitor boxes and within milk carton traps baited with ammonium, eugenol or water. Milk carton traps contained *S. feltiae* '27' within a sand-polyacrylamide mixture and attractants (baits) were positioned alongside the trap. Sticky tapes (Pherocon-Am) attached to trap posts indicated a large, peak emergence on June 10, with erratic emergence patterns thereafter due to wind and rain patterns. Despite the abnormal emergence pattern, we were able to demonstrate that flies were infected by *S. feltiae* and that these nematodes survived at least 7 days within traps under field conditions. Eugenol was noted as having some potential as an attractant even though a statistical comparison of treatments was precluded by abnormal adult flight timing.

During the 1994 season, we plan to modify the trap and monitor designs, the assessment of various potential attractants, and the choice of nematode strains. The ability to decrease adult numbers prior to oviposition could significantly reduce resultant larval numbers on nearby seedlings.

## ABSTRACT OF PAPERS PUBLISHED OR APPROVED FOR PUBLICATION

**SAUNDERS, J. W.** 1993. Notice of release of smooth root germplasm with mutant form of ALS enzyme - EL-49

EL-49 is being released as a germplasm source for breeders to use in the development of smooth root breeding lines and cultivars. EL-49 is S<sub>1</sub> seed produced by selfing clone 10-181. Clone 10-181 was developed from a cross of clones 79B15x069 (the near cytoplasmic male sterile equivalent to EL-48) and CR1-AJ, followed by two successive outcrosses to two individual smooth root selections from smooth root line SP85700. Two resulting BC<sub>1</sub> individuals were then sibmated to produce the population out of which clone 10-181 was selected. EL-49 is a multigerm diploid with N cytoplasm, segregating for red and green hypocotyl. The parental clone 10-181 is highly self-fertile. EL-49 is expected to be used by breeders interested in the smooth-rooted characteristic. Less dirt clinging to beets during harvesting results in lower tare dirt percentage, a sanitation benefit in the face of the spread of the rhizomania disease across the U.S. There is also the potential for peel removal prior to processing as well as the likelihood of reduced post-harvest respiratory and rot losses. EL-49 is homozygous for a mutant form of the acetohydroxyacid synthase enzyme which can be used as a marker to confirm hybridization when EL-49 is used as a parent.

**HART, S. E., J. W. SAUNDERS, AND D. PENNER.** 1993. Herbicide resistant crops from cell selection. Reviews of Weed Science (Accepted 5/93, in Press).

Herbicide resistant cell lines have been selected using somatic cell selection in eleven crop species (tobacco, tomato, alfalfa, corn, white clover, flax, sugarbeet, carrot, canola, birdsfoot trefoil, petunia). Resistance has been obtained to herbicides of quite different modes of action, including ALS inhibition, lipid biosynthesis inhibition, as well as triazine, thiocarbamate, and growth regulator herbicides. Depending on individual cases, the resistances vary for availability in whole plants, for stability, for mode of inheritance, for origin by way of artificial mutagens, and for single or multi-step selective procedure.

**HART, S. E., J. W. SAUNDERS, AND D. PENNER.** 1993. Initial field evaluation of sulfonylurea herbicide resistant sugarbeet from somatic-cell selection. J. Sugar Beet Res. 31:(1+2)(Accepted 2/4/94)

Field studies were conducted with a sugarbeet (*Beta vulgaris* L.) breeding line segregating for monogenic dominant sulfonylurea herbicide resistance conditioned by the Sur<sub>1</sub> allele and obtained from somatic cell selection. Sulfonylurea herbicide resistant and susceptible sublines were compared to each other and to the commercially available susceptible cultivar MONO-HY E4 in regards to root yield, sucrose percentage, and processing purity. In addition, the response of MONO-HY E4 and the sulfonylurea resistant and susceptible counterparts to simulated carryover sulfonylurea residues in soil and to postemergence (POST) applications of selected sulfonylurea herbicides was evaluated. In the absence of herbicides, counterpart resistant and susceptible sugarbeet produced similar root yield,

sucrose percentage, and clear juice purity at both locations. Nicosulfuron applied preplant incorporated (PPI) at 9 g ai ha<sup>-1</sup> to simulate carryover in soil had no effect on the growth of sugarbeets from the resistant population or from the susceptible MONO-HY E-4 cultivar seeded immediately after application. Primisulfuron and chlorimuron applied PPI at 10 and 3 g ai ha<sup>-1</sup>, respectively, caused over 95% visible injury to the susceptible MONO-HY E-4 sugarbeet 6 weeks after treatment (WAT) but had no adverse effect on the growth of resistant sugarbeet. POST application of primisulfuron at 40 and 80 g ai ha<sup>-1</sup>, and thifensulfuron at 4 and 8 g ha<sup>-1</sup> (one and two times the normal field use rate for corn and soybean, respectively) caused less than 15% visible injury to the resistant sugarbeet 4 WAT, but caused severe injury to the susceptible MONO-HY E-4 sugarbeet. The sulfonylurea resistant sugarbeet was tolerant to POST applications of primisulfuron at four times and thifensulfuron at two times the field use rate. This magnitude of resistance is great enough for effective use of primisulfuron and thifensulfuron for weed control in sulfonylurea resistant sugarbeet.

**THEURER, J. C.** 1994. Agronomic comparison of different types of smooth root and "soil free" sugarbeets. J. Sugar Beet Res. 31:Accepted 12/3/93.

Field experiments were conducted for three years to compare growth characteristics and agronomic performance of sugarbeet genotypes differing in taproot architecture. Genotypes studied were MH E4 and either ACH 176 or ACH 185, commercial hybrids with standard grooved taproots; SR 87, a conical-shaped smooth root (SR) line developed by USDA, ARS at East Lansing, MI; A90MM, a globe-shaped SR experimental triploid hybrid from the Netherlands; and Univers, a European commercial variety with shallow root grooves and low soil tare at harvest. Taproot growth was primarily below the soil level for all genotypes except A90MM, which had only about 50% of the root underground. Averaged over years, root yield for SR 87 was 79.86 Mg ha<sup>-1</sup>, significantly greater than the 70.72, 72.33, and 62.38 Mg ha<sup>-1</sup> for A90MM, Univers and MH E4, respectively. Sucrose percentage for SR87 (15.31%) and A90MM (14.50%) was 1% - 2% lower than for U. S. commercial varieties. SR87 was equal to the commercial varieties in sucrose yield per hectare. There was little difference among all of the genotypes studied in clear juice purity. A90MM had about half the quantity of soil adhering to taproots as did SR87 and Univers and about one-fourth of that for standard grooved root varieties. A90MM produced 42 gm dry matter of top per plant compared to 75, 106, 108 and 121 gm for Univers, SR 87, MH E4, and ACH 185, respectively. Globe-shaped roots of A90MM were harvested with significantly less soil tare than conical-shaped SR beets. However, they had the disadvantage of often being dislodged from the row when tops were removed with a rotobeaeter. Using current sugarbeet harvesters the conical-shaped smooth root beets would be the more desirable architecture.

**THEURER, J. C.** 1993. Pre-Breeding for root architecture. J. Sugar Beet Res. 30:(4). (Accepted 12/30/93)

Economic improvement of sugarbeet (*Beta vulgaris*) field production and processing can be enhanced if traditional architecture of the sugarbeet is modified to a smooth root (SR) beet. Root shape of sugarbeet is a multigenic character and several generations of

breeding are needed to reach any degree of homozygosity. In recent years conical-shaped SR beets have been developed in the eastern U. S., and in the Netherlands globe-shaped beets have been developed by crossing table beet with sugarbeet followed by phenotypic recurrent selection. SR beets tend to have fewer fibrous rootlets near the soil surface than for traditional grooved-root beets but rootlets still proliferate mainly along two vertical planes. SR testcross progenies have shown less taproot tip breakage than for a commercial hybrid cultivar. Root yield of current SR genotypes and experimental hybrids has been equal or superior to that of commercial cultivars, but sucrose content has been 1-3 percentage points less. Soil tare for SR genotypes has ranged from 30% to 70% less than for current commercial cultivars with traditional architecture. Globe-shaped beets have lower soil tare than conical-shaped SR beets. However, SR beets bred with conical-shaped are more desirable than globe-shaped roots using current sugarbeet harvesting equipment, because globe-shaped beets grow more out of the soil, often are dislodged from the row when tops are flailed, and may not be picked up by the harvester.

## SOMATIC CELL SELECTION STUDIES

### Somatic Cell Selection for Resistance to Methionine Sulfoximine and to Ethionine

Joseph W. Saunders and Philipp Kapranov

One goal was to select for in vitro occurring variants having increased levels of glutamine synthetase. Selection for resistance to a specific inhibitor of glutamine synthetase (GS), L-methionine sulfoximine (MSO), was chosen on the basis of reported isolation of GS overproducing cell lines in a number of plant species following step-wise (chronic) selection for tolerance to MSO or another GS inhibitor, phosphinothricin. We employed direct selection, which has been successful in producing cell lines overproducing GS or other inhibitor-targeted enzymes due to gene amplification in animal systems, and in producing an uncharacterized MSO resistance in tobacco (Carlson, 1973).

Sieved suspension cultures of REL-1 were plated on media containing 2-5 times the LD<sub>100</sub> concentration of MSO. A total of  $1.5 \times 10^8$  cell clusters (7600 dishes) were plated. No true resistant isolates have been obtained. We then tried chronic (stepwise) selection. The first round of selection resulted in adaptation of cultures (the criterion was normal growth) to the LD<sub>50</sub> concentration, followed by a doubling of the concentration of MSO with each succeeding round of chronic selection. We ultimately obtained cultures capable of normal growth at as high as 12.5 times the LD<sub>100</sub> (the lowest lethal) concentration. However these cultures had completely lost their ability to regenerate shoots after their 6 months in culture. Shoots could be regenerated from cultures adapted only as far as 0.8 times the LD<sub>100</sub> (3rd round of chronic selection). Now we are propagating those shoots, which look normal, for further trials. We have not been able to regenerate shoots from cultures adapted to higher levels of MSO, despite extensive efforts: a total of 3000 dishes plated with cultures adapted to various levels of MSO.

Selection for resistance to ethionine, an analog of methionine, is the other part of the current selection efforts. Methionine was demonstrated by Winner (1966) to protect beets in hydroponic culture from Aphanomyces attack. As some ethionine resistant mutants in other species have elevated methionine levels, we hope to test whether variant cells selected for ethionine resistance have elevated methionine levels in the whole plant and whether this is associated with greater tolerance of the Aphanomyces pathogen.

Nearly  $1 \times 10^6$  cell clusters have been plated so far, most with an acute exposure to lethal levels of the ethionine. One resistant callus line has resulted, and we are attempting to get this to regenerate shoots now.

## **Alternate Nitrogen Sources for Callus Induction from Leaf Discs and for Subsequent Bud Regeneration**

Joseph W. Saunders and Chia-Jung Tsai

Nitrogen is an important element for stimulating early seedling growth and rapid development of the sugarbeet canopy. However, an excess of nitrogen near the end of the growing season results in lower sucrose percentage in the taproot, and higher levels of impurities that interfere with sugar crystallization in the processing factory. Furthermore, nitrate levels in groundwater have become a matter of public concern and could probably be decreased by avoiding excessive nitrogen application relative to efficient crop needs.

Nitrogen is taken up by the beet crop primarily in the form of nitrate. Nitrate passes through the root unaltered, and is reduced in photosynthetic tissues, ending up as glutamine (Burba, 1983). Roots rely for their organic nitrogen on the downshipment of organic foliar nitrogen, primarily glutamine. From a beet root processing point of view, glutamine/glutamate is major component of clear juice impurity. It is also the key hub of active organic nitrogen distribution in the cell. Glutamine/glutamate concentration in the roots is probably regulated by multiple mechanisms.

Mutations of either regulation or enzyme function for the steps of nitrogen uptake, transport, reduction and interconversion could be of interest to the beet industry if these mutations were associated with (a) greater fertilizer use efficiency, (b) greater sugar percentage and juice purity (in the case of poorer efficiency), or (c) simply lower nitrogenous clear juice impurity levels (if glutamine/glutamate pool levels in the root are lower).

There are few plant mutations known to affect nitrogen assimilation without drastic effects on plant vigor. One example involves the two gene system differentiating burley and flue-cured tobacco that confers a four-fold difference in nitrogen use efficiency, and is expressed primarily in the shoot (Crafts-Brandner et al., 1987). This genetic variation occurred naturally.

Tissue culture provides a way to generate variants in nitrogen metabolism, either by spontaneous somaclonal variation or by use of a mutagen. For example, Heimer and Filner (1970) selected a tobacco cell line that was resistant to threonine inhibition of growth on nitrate as sole nitrogen (N) source. In sugarbeet, Sabir et al., (1992) identified a glutamate dehydrogenase overproducer in a random growout of regenerant plants. In neither case was seed available for field testing.

We have developed a system for plating out sugarbeet cells of an amenable genotype (REL-1) for selection of variants and regeneration of plants from these cells (Saunders et al., 1990). This system was effective in recovery of a sulfonylurea herbicide resistance factor (Saunders et al., 1992) and in subsequent recovery of additional herbicide resistance factors when the system was employed by weed scientists (unpublished). We have recently been developing selective regimes to efficiently select for variants of nitrogen assimilation that might enhance agronomic performance with respect to N use efficiency or processing purity.

Three types of selective regimes were identified earlier: (1) selection for growth in the presence of inhibitors of nitrogen assimilation steps when the traditional tissue culture N mix of nitrate and ammonium is provided to the cells, (2) selection for growth in the presence of a sole nitrogen source and an inhibitor of the utilization of that source (the vulnerability scheme), (3) selection for ability to utilize an otherwise unusable sole carbon or nitrogen source.

All three of these types of positive selection can be considered qualitative methods,

because they identify the rare surviving individual colony in an acute (one time) exposure to the selective environment. However, another type of positive selection relies on the fact that in a growing cell population, the arising of new genetic variation providing advantages to utilizing the ambient nutrients will lead to a disproportionate (quantitative) increase in the frequency of those variant cells. This disproportionate increase should also be reflected in the population of regenerate plants. In practice, to identify some of these variants will require a grow out of regenerate plants and some kind of progeny test. Because this type of selection targets no specific enzyme, involves changes in cell population gene frequency, and relies on the progeny test to identify variants in field performance, its efficiency is low. Its advantage would be that the initial stage of performance identification would be very close to that of final application, i.e., the field as contrasted to the petri dish.

To this end we tested various sole nitrogen sources for their ability to support induction of callus from leaf discs and subsequent regeneration of buds or shoots from that callus without transfer. This is the first step we use in our standard system for generating callus derived plants for a grow out.

The experiment was run twice, once with leaves from REL-1 plants grown in a growth chamber and the second time from REL-1 plants grown in the greenhouse in November, without supplemental light. There were some differences in the outcome which might reflect differences in leaf physiological condition at the time of sampling, for example, due to light quantity per day.

The Murashige-Skoog N mix gave the best callusing and bud regeneration response, followed next by glutamine at 15 mM (Table 1). Buds were also produced on ammonium, urea and choline to a lesser extent. Paralleling the earlier lack of response in suspension plateout (SP) and shoot culture (SC) growth, betaine and proline supported no callus induction. Glutamate was also incapable of supporting leaf disc callus induction, similar to its response for SC but contrasting to its moderate SP growth. Most surprising was the poor support offered by nitrate, which earlier had given moderate growth of SP and SC. One explanation of this would be that the typical partially expanded leaves used as sources of discs have not developed very high nitrate reductase activity levels because they are still in a net assimilate importation stage on the plant.

It is apparent though that by using glutamine as a sole N source, callus induction and bud regeneration can occur at high enough levels to permit efficient recovery of plants. If there has been quantitative selection for cell variants better able to grow and utilize glutamine, this could lead to enhanced recovery of respective plants in a growout and progeny test.

## 1993 EXPERIMENTS OF GENOTYPE X NITROGEN RESPONSE

J. C. Theurer and J. W. Saunders

### EVALUATION OF DIVERSE GENOTYPES FOR POTENTIAL NITROGEN USE EFFICIENCY.

Nitrogen fertilization is an important aspect for growing a good sugarbeet crop. Sufficient N is required for the beet to make rapid growth in the spring and to quickly develop a canopy of leaves for photosynthesis, further plant growth, and sucrose accumulation. Excess N at harvest results in higher impurities in the root and more difficulty in processing to sugar. Also, in recent years the public has expressed considerable concern regarding the quantity of nitrogenous and other chemical residuals in soils and water. In 1990 a research program was initiated to evaluate diverse genotypes for their potential difference in tolerance to high N or their efficiency for high sugar production with low nitrogen availability. Minor differences in N response were noted for some genotypes in past years. In 1993 we continued this research by evaluating some additional diverse genotypes for their response to differential nitrogen fertilization.

Sixteen highly diverse genotypes (Table 1) of sugarbeet including one selection with Beta macrocarpa parentage and two with B. maritima parentage were planted in a randomized block experiment of four replications at the Bean and Beet Research Farm on May 14, 1993. Individual plots were two rows 28" apart and 30' in length. Adequate phosphorus and potassium fertilizer was applied pre-plant but no N fertilizer was applied until after thinning. In mid-July the plots were fertilized with zero, 90# ammonium nitrate/acre (optimum nitrogen fertilization for Michigan), or 180# ammonium nitrate/acre in accordance with the randomized block field plan. The experiment was machine harvested on October 7, 1993. The row length of each plot was measured just prior to harvest to adjust plot size for any skips within the rows. All roots in each plot were weighed to determine root yield and RWSA. A fifteen beet random sample of roots was taken from each plot to determine sucrose percentage, CJP percentage and meq amino N per 100 g sugar. These determinations were made by Michigan Sugar Company personnel at their research lab in Carrollton, MI. Data was summarized and analyzed using the MSTAT statistical program developed at Michigan State University.

### RESULTS

Summed over genotypes, when N was increased, root weight, recoverable sugar per acre (RWSA) and meq amino N/100g. sugar in the root at harvest were increased, while sugar content, recoverable sugar per ton (RWST) and clear juice purity (CJP) were decreased (Table 2). Significant differences were also noted between the genotypes (Table 3). The nitrogen level x genotype interactions were significantly different for all variables except for recoverable sugar per acre (RWSA) (Table 4). All genotypes showed an increase in RWSA with an increase in N fertilization, but yield differences were not significant for any of them. Four genotypes (90318, Ovana, A93-2, A93-5) had significantly higher RWST at the zero N level than at higher N levels. The other twelve genotypes, had significantly lower RWST at the 180# N rate than at the zero rate and six of these genotypes (ACH185, 88S3-00, 85320-0, 85576-0, A93-3, USH20) also were significantly lower in RWST at the 180# level than at the 90# N level. Ten entries produced significantly higher root yield at 180# N, than at the zero N level. For two of these genotypes

(88S3-00, A93-10), the 180# level also showed significant yield increase over the 90# N level. Root yield increased with increased fertilizer for the other six genotypes, but differences were not significant. Two genotypes (A93-2, A93-5) had significantly higher sucrose content with zero fertilization than with either 90# or 180#/ acre fertilizer level. Ovana, the genotype with the lowest sucrose content, was the only genotype that had similar sucrose percentages at all N levels. The majority of the genotypes had significantly lower sucrose content when grown in the 180# N environment. Seven of the genotypes (91270M,88S3-00,85320-0,85576-0,A93-3,A93-10,USH20)were significantly lower in sucrose percentage at the 180# rate compared to when they were grown with the standard 90#/acre N. Entries 88S3-00, 90318, 85576-0, A93-2, and A93-5 showed significantly higher purity with zero versus higher levels of fertilization. The 180# fertilization rate resulted in significant increases in the meq amino N/ gram sucrose in the beet root at harvest for the majority of the genotypes. The commercial cultivars ACH 185 and Beta 5315 showed little difference in amino N across fertilizer levels, while most genotypes showed an increase in amino N as the level of fertilizer increased. Only genotype A93-5, a progeny from L53 x B. maritima, showed significant step wise increases in amino N from zero to 90# and 90# to 180#.

Genotypes that have the best prospects for producing good yields, and high sucrose content under a low N environment appear to be 91270M, a selection from L19, and 91B21, an East Lansing selection for high RWST. None of the genotypes showed good prospect for finding germplasm that could utilize abundant nitrogen and still produce good sugar content with acceptable quantities of nitrogenous impurities in the root. Ovana and A93-2 genotypes showed the least sensitivity to loss of sucrose when N level is increased from 90#/acre to 180#/acre. Ovana, however, has very low sugar content to begin with, and partitioning to root growth versus sucrose accumulation may have an effect of keeping the sucrose content fairly stable in this fodder beet. Three genotypes (88S3-00, USH 20, and 85576-0) showed more sensitivity than others when the N level was raised from 90# to 180#/acre, resulting in reductions in sugar content of 2.6, 1.7 and 1.5 percentage points respectively. Two genotypes (L19 Select, and A93-3) had good sugar yield (RWSA) and high sugar content at the zero N level. ACH 185, Beta 5315, and 88S3-00 also had high sucrose percentage under the zero N treatment.

## **SELECTION FOR HIGH SUCROSE PERCENTAGE, HIGH AMINO N AND LOW AMINO N IN THE L19 HIGH SUCROSE GENOTYPE.**

Past years experiments have demonstrated that the L19 genotype, which has very high sucrose percentage, also has a high accumulation of amino N in the roots at harvest. High sucrose, high amino N, and low amino N selections were made from two field block plantings of L19 in 1990. One field block had zero nitrogen applied during the growing season; and the other block was fertilized with 180# available N per acre, about twice the recommended rate for sugarbeets grown in Michigan. In 1992 five progenies selected from the high sugar line L19 grown in low and high N field plots were evaluated in the field along with the L19 parent line. The study was done to assay the effect of N fertilizer on the relationship of sucrose percentage and amino N impurities in the beet root at harvest in this high sucrose germplasm. In 1993 we repeated the experiment. Three of the selections tested were from seed increases of beets selected for high sucrose, high amino N, and low amino N when grown in a low nitrogen environment. The two other progenies were high sucrose and high amino N selections from beets grown under high N (180#/acre) fertilization. Insufficient seed was available for field planting of low amino N selection grown in a high N environment. The 1993 field trial was fertilized at the rate of 90# available N/acre, the recommended rate for sugarbeets grown in Michigan. Individual plot size for each entry was two rows 28" apart and 30' in length. Sufficient residual seed was available to plant only three replications. The experiment was machine harvested October 7, 1993. All beets in a plot were weighed for root yield and a random 15 beet sample was selected to determine sucrose percentage, purity and meq amino N/100 grams of sugar. The latter determinations were made by Michigan Sugar Company personnel in their laboratory at Carrollton, MI.

## **RESULTS**

The data from the 1993 planting was similar to that collected in 1992 (see Table 7 p.E25 1992 Research Report). The L19 parent line again had the largest root yield and recoverable sugar per acre (RWSA) (Table 6). The high sucrose selection made under low N (92S19-01) had the lowest root weight both years, and was lowest in RWSA in 1993. The high amino N selection from the high N field plot, 92N19-04, was equal to the L19 parent in 1992 in RWSA, but it had significantly lower sugar yield than L19 in 1993. The high sucrose selection 92S19-01, as expected, had the highest sucrose percentage and recoverable sucrose per ton (RWST) for both years. There were no differences in clear juice purity percentages between all entries in 1992. However, the L19 parent and the low amino N selection 92N19-01 had significantly higher CJP percentage in 1993 than 92N19-04 and 92SN19-01, the high Amino N selections. The high Amino N selection made in the low N field (92SN19-01) was consistent over years in having the highest meq amino N/100 g. sugar. The low amino selection, 2N19-01, had the lowest amino N values both years. The data shows that selection for amino N can be very effective. It also demonstrates a close association with CJP percentage and the meq amino N/per 100 g. sugar in the root at harvest. The data also suggest independence of the genetic factors governing sucrose accumulation and amino N impurity level. They demonstrate that the characteristically high amino N found in the root of L19 at harvest can be greatly modified by selection for low amino low N retention in the mature sugarbeet root.

## EVALUATION OF SUGARBEET SMOOTH ROOT BREEDING LINES AND EXPERIMENTAL HYBRIDS - 1993

J. C. Theurer

Excellent smooth root architected beets have been developed, but they do not have the level of sucrose percentage nor the disease resistance that is desired for today's commercial varieties. In 1993 we continued our efforts to enhance these characteristics in SR germplasm. Selections, experimental hybrids, and SR populations were evaluated for their agronomic performance. A SR nursery with over 3000 plants was screened, and selections having excellent smoothness of root and sucrose percentage above that of the check cultivar ACH 185 were again made for seed increase for the next selection cycle. Some excellent resistance to Cercospora leafspot was also noted this year.

### EVALUATION OF A GROUP OF HIGH SUCROSE SMOOTH ROOT GENOTYPES.

This experiment was designed to evaluate the agronomic performance of a group of high sucrose smooth root (SR) progenies. Individual beets with good SR shape and sucrose percentage on a fresh weight basis ranging from 100-117% of that for ACH 185 were selected from the 1991 SR breeding nursery. Seed was produced in groups with 3-10 roots in each group, depending upon the pedigree of the breeding material. The eleven SR progenies plus ACH 185 commercial hybrid check were planted in two row plots with rows 28" apart in a 6 replicate field trial. Just prior to harvest the length of each plot row was measured and adjustments made to correct the plot area for skips that occurred within the row. Harvest by machine was done on October 7, 1993. All beets in each plot were weighed to determine the tons per acre, and recoverable sugar per acre (RSA). A fifteen beet random sample of roots was taken from each plot for sugar and purity analyses. Sugar percentage and clear juice purity were determined by Michigan Sugar Company personnel in their research laboratory at Carrollton, MI using standard thin juice methods. A root smoothness score was estimated for each plot by observing the beets as they fell into the weighing basket. Beets were scored on a 1-5 scale as defined below:

- 1 = Very smooth taproot, no grooves, broad fibrous root zone
- 2 = Smooth, slightly grooved taproot, narrow fibrous root zone
- 3 = Partially smooth, grooved, heavy fibrous non-branching taproot
- 4 = Rough shaped taproot, deep grooves, heavy fibrous roots with some sprangling
- 5 = Very rough, very deep grooves, multiple branched taproot

Data was analyzed using the Michigan State University MSTAT statistical program.

## RESULTS

With the exception of one SR progeny, the SR lines were not different from ACH 185 in recoverable sugar per acre (RWST)(Table 1). Five SR progenies slightly exceeded the check cultivar in root weight, however none of the 11 yielded significantly more or less than the check. ACH 185 had significantly the highest recoverable sugar per ton (RWST) and the highest sucrose percentage. Progenies 92HS10, 92HS33, and 92HS46 were the SR progenies with the highest sucrose content. These progenies were developed from groups of selected individual roots, which averaged 112%, 113%, and 110% of the sucrose of ACH 185 on a fresh weight basis. All but two SR progenies were equal to the check in clear juice purity (CJP). Only nine of the SR lines were significantly lower in smooth root score than ACH 185. Progeny 92HS45 had the best SR architecture. The best progenies for continued selection based upon the desirable characteristics of good sugar yield, high sucrose content and SR architecture, appear to be 92HS10, 92HS30, 92HS32 and 92HS33.

### EVALUATION OF GENOTYPES DERIVED FROM INDIVIDUAL BEET SELECTIONS MADE IN THE 1992 SMOOTH ROOT BREEDING NURSERY.

This experiment was an agronomic evaluation of high sucrose SR progenies derived from individual beet selections made in the 1992 SR breeding nursery. Selections were made on the basis of good SR type and sucrose content which was equal or better than that of ACH 185. Seedlots were produced in the 1992-93 winter greenhouse and planted in field trials at the Bean and Beet Research Farm near Saginaw, MI on May 21, 1993. Seed numbers and a descriptive background of the plant material are listed in Table 2. The experiment consisted of; 20 SR progenies and two commercial cultivars, ACH 185 and MH E4. The entries were seeded in two row plots with rows 28" apart in a random block design of 6 replications. The field trial was harvested October 5, 1993 and other data collected in the same manner as cited above.

## RESULTS

Fourteen of the SR entries were equal to ACH 185 in RWSA and six SR entries were inferior in sugar yield (Table 2). Four entries had root weigh significantly higher than the ACH 185 commercial cultivar and two were inferior in tonnage. One SR progeny, 93HS30, was significantly better in RWST and sucrose percentage than all other entries in the test. Four other SR progenies, 93HS27, 93HS37, 93HS35-8, and 92HS33 were equal to ACH 185 in sucrose percentage and RWST, Only two progenies were significantly lower than MH E4 for sucrose and RWST. Very little difference was noted in the CJP for the 22 entries. The smoothness scores ranged from 1.9 to 3.3 with, as expected, the commercial cultivars showing the highest scores. Unfortunately , SR progeny 93HS30 that had the highest sucrose percentage had poor root architecture, with a smoothness score no different than the commercial varieties. Three SR progenies (93HS35-8, 93HS35 and 93HS27) showed excellent performance when one considers breeding for the combined characteristics of smooth root architecture, high sucrose content and good root yield. Interesting observations were made for some SR entries of related parentage.

Progenies 93HS30, 93HS31, and 93HS37 all were derived from SR lines crossed to L19 inbred. Entry 93HS31 had high yield, and low sucrose content, while the two other progenies had the opposite, high sucrose content and low root yield. Entry 93HS32 and 93HS33 are similar except that 92HS33 also had some L53 germplasm in its background. Entry 92HS32 had high root weight and RWSA, while 92HS33 was considerably higher in sucrose content and RWST.

## **FIELD EVALUATION OF OPEN POLLINATED POPULATIONS OF SMOOTH ROOT BEETS WITH DISEASE RESISTANCE, OR MULTIPLE SOURCE SUCROSE ENHANCEMENT.**

A field evaluation was made this year to assess the agronomic performance of 11 SR populations which had been derived from SR material crossed in previous years to other sugarbeet lines having good disease resistance or high sucrose content. There were 12 entries in the test; four (91HS1-00, 92HS11, 92HS13, 92HS14) were crosses of a selected SR genotype with lines having high sucrose content; three (92HS6, 92HS7, and 92HS8) were crosses of SR germplasm with Rhizoctonia and Cercospora leafspot resistant lines, and three (92HS10, 92HS12, 92HS15) were from SR lines crossed with multiple sources of high sucrose content. ACH 185 was included in the field trial as a check. The twelve entries were planted at the B&B Bean and Beet Research Farm on May 14, 1993. Plots were two rows 28" apart and 30" in length and there were six replicates of a random block design. The experiment was harvested and samples taken for sucrose and CJP using the same methods as cited previously.

## **RESULTS**

RWSA, root weight, and CJP for the 12 entries were quite similar and they varied little from the performance of the check cultivar ACH 185. There were marked differences, however, for RWST, sucrose percentage and smoothness of root score (Table 3). Entry 92HS15, a population derived from the 8562 SR source crossed with high sucrose sources of L19, L53, and C51 showed the best performance. This SR composite had the highest RWSA and root weight of all of the entries and was among the highest in RWST, sucrose content and CJP percentage. It scored a 2.5 in smoothness in comparison to 3.5 for ACH 185 and 2.0 for entry 6, which had the lowest smoothness score and the most desirable root shape of all entries in the experiment. Entry 92HS10, with C40, L19, and L53 sugar sources in its parentage was excellent for sucrose content and RWST, but it was low in root yield, and RWSA and had a smoothness score no different than that of ACH 185. Entry 92HS13 and 92HS14 were other populations that showed excellent smoothness of root. Entry 92HS13 also had high CJP percentage and sucrose content 1% lower than the check.

## **EVALUATION OF EXPERIMENTAL HYBRIDS FROM CMS X SMOOTH ROOT GENOTYPES**

In this experiment we evaluated the relative performance of four SR lines for combining ability when they were crossed to some of the same CMS inbred lines. Planting was made at the Bean and Beet Research Farm on May 14, 1993. The individual plots were two rows 28" apart and 30' in length in 4 replications of a random block design. ACH 185 was included as a check. Harvest was made on October 6, 1993 and data was collected in accord with standard procedure listed previously.

## RESULTS

There was very little variation between the experimental SR hybrids with the exception for smoothness of root score (Table 4). ACH 185 was significantly better than all other entries for RWSA, RWST, and sucrose percentage. Only four SR hybrids, three of them being crosses with SR87, were significantly better than ACH 185 for smoothness of root score.

### FIELD EVALUATION OF EIGHT ADVANCED SMOOTH ROOT GENOTYPES.

The agronomic performance of eight advanced SR breeding lines were compared with that of two commercial hybrid cultivars, MH E4 and ACH 185, and with two released sources of SR germplasm, SR87 and SR80, in a randomized block experiment of four replications. The entries were planted in two row plots 28" apart and 30' in length on May 14, 1993 at the B&B Research Farm. They were harvested on October 7, 1993 using the same procedures as outlined previously.

## RESULTS

With the exception of 90HS2 and SR80, there was little difference between the RWSA of the commercial cultivars and the SR lines in this field trial (Table 5). These two lines were not only significantly lower in RWSA than both checks, but they were also lower than SR lines 91H1-00, and 89H700. Five of the SR lines had better root yield than ACH 185, but only one, 89H700, exceeded the root yield of MH E4. ACH 185 had higher sucrose percentage and RWST than all entries. Three of the SR lines, however, were equal to the MH E4 hybrid in their sucrose content and RWST. No differences were observed between the SR lines for CJP percentage, but SR87 and 89H700 were significantly lower in CJP percentage than ACH 185. Two of the SR lines, 89H700 and 91H5, had significantly lower root smoothness scores than SR87. The genotype 91H5 has promise for further breeding and selection, but 89H700 is too low in sucrose content (2.6% lower than ACH 185). Three additional SR lines, 90HS2, 90H3-00 and 90H11, also had significantly better root smoothness score than ACH 185. Unfortunately 90HS2 is extremely low in root yield and 90HS3-00 and 90H11 are low in sucrose content. In 1992 field trials, SR line 91H4 had equal RWSA, root weight and CJP percentage and only one percentage point less sucrose than ACH 185 and it was looked upon at that time as a potential SR release. (See 85131 select in table 3 of 1992 Research Report p. E14). However, this line did not maintain as favorable relationship to ACH 185 this year. A general observation is that lines with the highest sucrose content tended to have the lowest root smoothness score and those with excellent root shape were most often among the genotypes with the lowest sucrose.

Table 1. Sucrose yield, root yield, sucrose percentage, CJP percentage, and smoothness of root score for a group of high sucrose SR genotypes. B&B Farm 1993.

## **FIELD EVALUATION OF THE RELATIVE PERFORMANCE AND COMBINING ABILITY OF AN AGRONOMIC SELECTION FROM L19 VERSUS L19.**

J.C. Theurer

L19 inbred has outstanding sucrose content, but it also harbors some undesirable characteristics. Many of the plants have multiple crowns and taproots are frequently deep grooved and/or too small in size. A selection of approximately 100 roots with single crowns, good root shape and root size equal to the mean of the parent line was made from a field planting in 1991 in an attempt to improve the agronomic characteristics of L19. Seed increase was made of the selected roots and at the same time CMS lines were also planted within the isolation block to obtain F1 hybrids to evaluate the combining ability of the new L19 selection. Five experimental hybrids, L19, L19 Select, and two commercial hybrid cultivars, MH E4 and ACH 185 were planted May 14th in a field experiment at the Bean and Beet Research Farm near Saginaw, MI in 1993. The nine entries were planted in two row plots with rows 28" apart and 30' in length and there were six replications. The experiment was harvested on October 7, 1993 using methods as outlined in Experiment 931 above.

### **RESULTS**

The nine entries formed two groupings for RWSA (Table 8). MH E4, and the two L19 inbreds were significantly lower in RWSA than the other six entries. The L19 lines and ACH 185 had the highest sucrose percentage and RWST. WC91269, a BMC CMS x L19 Select hybrid, was highest in root yield and also the entry with the lowest sucrose content. WC91268 (576CMS crossed to L19 Select), showed the best combining ability of the experimental hybrids for sucrose content and CJP percentage. MH E4 was lowest in amino N in the root at harvest and the two L19 lines and WC91269 were highest in amino N. Although there were no significant differences between the L19 lines for any of the variables measured, there were indications showing a trend for change due to the selection pressure. L19 Select tended to show higher RWSA and yield, lower sucrose percentage, amino N, and higher CJP percentage than the L19 parent line. There was no apparent relationship between sucrose content and the meq amino N per 100g sucrose in the beet root. L19 and L19 Select exhibited high sucrose content and high amino N. ACH 185 showed high sucrose and relatively low amino N. WC91269 had low sucrose and high amino N. These results suggest that L19 and BMC plant material might be useful to study more fully the genetic and physiological relationship of sucrose accumulation and the retention of nitrogen impurities in the beet root.

Table 1. Sucrose yield, root yield, sucrose percentage, CJP percentage and meq amino N/ 100 grams sucrose for L19, L19 Select, and experimental CMS hybrids with L19 Sel. as a parent. B&B Farm 1993.

# RHIZOCTONIA ROOT ROT EVALUATION FOR COMMERCIAL AND EXPERIMENTAL HYBRIDS AT EAST LANSING, MI. 1993

J. C. Theurer, Lee Hubble and J. M. Halloin

Eighteen hybrid varieties plus two resistant checks, FC 710/5 and FC 712, and two susceptible checks, USH 23, and Universe were evaluated for their resistance to Rhizoctonia root rot in the disease nursery maintained at E. Lansing, MI. The natural source of inoculum in the soil was supplemented with an application of ground millet infected with R. solani, which was applied to the crowns of the beets just prior to layby. The roots were dug by hand in early November and scored for disease on a scale of 0 = no infection lesions to 4 = dead plant. There was only moderate infection in the nursery this year. In previous years, Univers was the most susceptible variety and FC 712, was the most resistant entry in the test.

# POTENTIAL BIOCONTROL OF RHIZOCTONIA ROOT ROT

J. C. Theurer and J. M. Halloin

In 1992 a comparison of 12 genotypes varying in Rhizoctonia resistance from highly susceptible to highly resistant gave evidence that there was some biocontrol for Rhizoctonia root rot (See 1992 Research Report p.E28). In 1993 we repeated the experiment. Twelve genotypes were planted on land (L1) that had been used for Rhizoctonia evaluation for several years, and on land (L2) outside the disease nursery but of similar soil type and only 300 meters from L1 at the Botany Research Farm at East Lansing. Six replications of the 12 entries were planted in single rows 28" apart and 25' in length. Special effort was taken again this year to provide as identical management practices as possible for the L1 and L2 units. The roots were dug by hand in early November and scored for disease on a scale of 0 = no infection lesions to 4 = dead plant. There was only moderate infection in the nursery this year. No differences were visually observed on the tops and crowns of the beets between L1 and L2. Significant differences were observed for genotypes, but the genotype x location interaction was non-significant (Table 2). This years results fail to confirm the 1992 conclusion that biocontrol of Rhizoctonia resistance has occurred in L1.

Table 2. Rhizoctonia root rot mean scores and percent diseased plants for 12 genotypes grown on land used many years as a Rhizoctonia disease nursery (L1) versus on land not previously used for Rhizoctonia evaluation (L2). East Lansing, MI. 1993.

**Cercospora Leafspot Evaluation of Smooth Root Selection  
Blocks, Experimental And Commercial Varieties  
Made at East Lansing 1993.**

J. C. Theurer and R. C. Zielke

A disease nursery has been used at East Lansing, MI for many years to evaluate and select breeding material which has resistance to Cercospora leafspot. The results of evaluations for a group of commercial hybrids, seed furnished by R. C. Zielke, and eight selection blocks of SR progenies, are given in this report. The commercial varieties were each planted in a randomized block experiment of 4 replications. Individual plots were single rows, 28" apart and 25' in length. The SR selection blocks consisted of 6 rows 28" apart and 25' in length. ACH 185 and the high leafspot resistant East Lansing line 86403 were planted adjacent to the selection blocks to serve as check varieties. When the full leaf canopy was developed on the beet plants, the nursery was inoculated by hand dusting with finely ground Cercospora infected leaves collected from the 1992 leafspot disease nursery. High humidity was maintained for 10 days after inoculation to enhance leafspot development by frequent misting of leaves using a sprinkler irrigation system with five nozzles.

Each plot in the disease nursery was scored for leafspot infection, five times during August and September. Only the final reading made on September 23, is shown in the tables in this report. Scores are on a 0 = no infection to 9 = dead plant basis.

Excellent infection occurred and significant difference in disease severity between genotypes was noted. Results for the SR selection blocks are shown in table 1 and for the commercial and experimental varieties in table 2. We plan to release WC 86403 as EL 50.

The Use of Green Manure Crops in Sugarbeet Rotation for Nematode Management by S. L. Hafez. . . . .	F3

# THE USE OF GREEN MANURE CROPS IN SUGARBEET ROTATION FOR NEMATODE MANAGEMENT

Saad L. Hafez

At least 29 species of plant parasitic nematodes within 16 genera can affect sugarbeet production. The overall sugarbeet yield losses attributed to nematodes is estimated to be in the range of 10-70%. The sugarbeet cyst nematode *Heterodera schachtii* account for most of the loss. Nematologists and plant pathologists agree that nematode are the major pest affecting sugarbeet production everywhere beets are grown commercially. The most common practices for sugarbeet nematode management is the use of nematicides (chemical control) at a cost of \$100 to \$300 per acre. The future availability of the most commonly used nematicides is uncertain because of health and environmental concern. These have come under attack by several environmental groups. Also there is a great public concern over the toxic hazards of these materials. Therefore, research emphasis needs to be directed towards developing environmentally safe alternative methods for sugarbeet nematode management.

A promising approach is the use of trap crops; plants that allow penetration yet are poor hosts for the nematode. Various plants with potential as trap crops have been shown to stimulate hatch, including sugarbeet (*Beta vulgaris*), oilseed radish (*Raphanus sativus* var. *oleifera*), white mustard (*Sinapis alba*), and buckwheat (*Fagopyrum esculentum*). Nematode-resistant cruciferous crops, particularly oilseed radish, may be useful as crop rotations that reduce *H. schachtii* populations. Cultivars of oilseed radish, white mustard, and buckwheat that stimulate hatch and depress *H. schachtii* reproduction have been developed in Europe. The research presented here was conducted to assess the usefulness of these cultivars for *H. schachtii* management in sugarbeet production.

## I. THE EFFECT OF OIL RADISH AND MUSTARD VARIETIES FALL PLANTED IN INFESTED FIELD ON SUGARBEET CYST NEMATODE *Heterodera schachtii* POPULATION.

Seven varieties of oil radish (*Raphanus sativus* var. *oleifera*) and white mustard (*Sinapis alba*) were planted following wheat in sugarbeet cyst nematode infested field in the fall of 1992 in Parma, Idaho. Each variety was replicated four times in a complete randomized block design and a fallow treatment was included as a control check for comparison. All varieties were mechanically chopped three months after planting. Roots and forages were incorporated in the soil by double disking. Soil samples before planting in the fall and in the following spring were collected for nematode assay. Results of nematode assay indicated that all varieties reduced the total number of eggs and larvae significantly (Table 1). Oil radish (Adagio var.) causes the highest % of reduction in comparison to fallow (51%). White mustard (Martigena var.) causes the lowest % of reduction (21%). The same test was repeated in the fall of 1993 at the same location to confirm results obtained in 1992-1993.

## II. THE EFFECT OF DIFFERENT OIL RADISH AND MUSTARD VARIETIES FALL PLANTED ON SUGARBEET ROOT YIELDS PLANTED IN THE FOLLOWING SEASON IN HEAVILY INFESTED FIELD.

Sugarbeet variety HM-WS-90 was planted following the oil radish and white mustard to evaluate their effect on sugarbeet yield. No nematicides were added to this field and standard insecticides for maggot control were applied at planting. Results showed that most oil radish and mustard varieties increased the sugarbeet yield significantly in comparison with the fallow treatment (Table 2).

## III. THE EFFECT OF DIFFERENT OIL RADISH AND MUSTARD VARIETIES ON SOIL NUTRIENT LEVELS.

Incorporating root and forage of the green manure crops will add substantial amount of humus which will enhance soil biological activity. Also, added humus substances to soil will enhance the activity of beneficial organisms and these will enhance soil fertility. Soil analysis before planting the green manure crops and after its incorporation showed significant improvement in soil fertility levels as shown in Tables 3 and 4.

The other secondary benefit observed in the green manure plots was that the weed population was reduced significantly where oil radish and white mustard were growing.

**Table 1. The effect of different oil radish and mustard varieties planted in the fall on sugarbeet cyst nematode *Heterodera schachtii* population. Parma, 1992-93.**

**HARVESON, R. M. and C. M. RUSH. 1993. The effect of *Aphanomyces* root rot and *Rhizomania* on sugar beet in a controlled environment. 27th Bien. Mtg. Amer. Soc. Sugar Beet Technol., Anaheim, CA, March 3-6, 1993.**

An experiment was conducted to determine the effect of *Aphanomyces cochlioides* and beet necrotic yellow vein virus (BNYVV), the causal agents of *Aphanomyces* root rot and rhizomania, respectively, on sugar beets. The test was performed in a controlled temperature box that was maintained at  $27 \pm 2$  C. Four treatments were employed, and consisted of soil containing *Aphanomyces*, BNYVV, both pathogens combined, and an uninfested control. Leaf weights and areas were taken twice during the test, at two and three months after planting. At harvest, tops were removed and the root profile was divided into equal 15-cm segments and washed. Roots collected from each segment were dried and weighed. At the time of the first reading for leaf weight and area, the control treatment was significantly different from the pathogen treatments. By the end of the test, significant differences were seen only between control and the treatment involving both pathogens. More damage was observed in dry top weight and taproot weight with the combined pathogen than with either one alone. Although the root rot rating for *A. cochlioides* was more severe than that of BNYVV, there was less weight reduction in the taproot. Root distribution was affected by pathogen treatments. In all segments, a greater amount of roots were recovered from uninfested controls than in all other treatments. In the middle segment, BNYVV produced more roots than *A. cochlioides*, but no differences were seen between the pathogen treatments in the bottom segment.

**HARVESON, R. M. and C. M. RUSH. 1993. Movement of viruliferous *Polymyxa betae* from a point source inoculation. 27th Bien. Mtg. Amer. Soc. Sugar Beet Technol., Anaheim, CA, March 3-6, 1993.**

Research was initiated in 1992 to study the spread of viruliferous *Polymyxa betae* from a known point source inoculation by irrigation and soil tillage. Untreated HH39 sugar beet seeds were planted 14 May 1992 in four 30 x 100 ft. borders, each containing twelve 30-inch beds. Inoculated seeds, used to establish the point source of infested soil, were obtained by coating seeds with a mixture of 2% methyl cellulose and powdered sugar beet roots containing BNYVV-infested *P. betae* cystosori. They were placed in the first ten feet of the two outside rows of each border. Half the plots were irrigated twice a month, and the other half once a month. Plant samples were collected twice and assayed by ELISA for BNYVV incidence. Soil samples were also collected and assayed. At the end of the first year, very little movement of BNYVV was detected outside of the inoculated areas. Establishing infection in the plots was successful because BNYVV was detected from the point source areas

in every assay. Future research will include collecting and assaying soil samples after land preparation for 1993, and repeating 1992 irrigation effect.

**HEIDEL, G. B. and C. M. RUSH. 1993. Distribution of beet necrotic yellow vein virus, beet distortion mosaic virus, and an unnamed soilborne sugar beet virus in Texas and New Mexico. Plant Dis. (Accepted for publication).**

The Texas sugar beet-growing area was surveyed to determine the incidence of beet necrotic yellow vein virus (BNYVV), beet distortion mosaic virus (BDMV) and an unnamed soilborne sugar beet virus designated as Texas 7 (Tx7). In late 1990, 302 soil samples were collected from seven Texas counties and one New Mexico county from fields scheduled for 1991 production. Sugar beet seed was planted in the soil samples, and root tissue was later harvested and tested by ELISA. Of 174 soil samples screened for BNYVV, 19 were positive. Of 128 samples tested for BNYVV and Tx7, 12 were positive for Tx7, 3 were positive for BNYVV and 23 were positive for both BNYVV and Tx7. One hundred fifty-nine soil samples were collected around symptomatic beets in 1991. Root tissue from sugar beets grown in the soil samples were tested for BNYVV, Tx7 and BDMV. Twenty samples were positive for Tx7, 27 were positive for BNYVV and 37 were positive for both Tx7 and BNYVV. Twelve of 72 sugar beets pulled at the time soil samples were collected were positive for BDMV. Sugar beets grown in soil samples collected from 8 of the 10 Texas sugar beet-growing counties were positive for BNYVV. Tx7 and BDMV were identified in the three major Texas sugar beet-growing counties. BDMV was identified in one New Mexico county. This is the first report of BDMV in New Mexico. No soil samples, including those collected directly around beets positive for BDMV, were positive for BDMV.

**HEIDEL, G. B. and C. M. RUSH. 1993. Incidence of beet necrotic yellow vein virus, beet distortion mosaic virus, and an unnamed soilborne sugar beet virus in Texas. 27th Bien. Mtg. Amer. Soc. Sugar Beet Technol., Anaheim, CA, March 3-6, 1993.**

The Texas sugar beet growing area was surveyed to determine the incidence of beet necrotic yellow vein virus (BNYVV), beet distortion mosaic virus (BDMV), and an unnamed soilborne sugar beet virus designated as Texas 7. In late 1990, Holly agronomists collected 302 soil samples from seven Texas counties and one New Mexico county from fields scheduled for 1991 production. Sugar beet seed was planted in the soil samples. Nine to ten weeks later, root tissue was harvested and tested by ELISA. Of 174 soil samples screened for BNYVV, 11% were positive. Of 128 samples tested for BNYVV and Texas 7, 8% were positive for Texas 7, 2% were positive for BNYVV and 17% were positive for BNYVV and Texas 7. One hundred fifty-nine soil samples were collected around symptomatic beets in 1991 and screened for BNYVV, Texas 7, and BDMV. Thirteen percent were positive for Texas 7, 16% were positive for BNYVV, and 23% were positive for Texas 7 and BNYVV. Seventeen percent of beets pulled at the time soil samples were collected were

positive for BDMV. Soil samples collected from 9 of the 10 Texas sugar beet-growing counties were positive for BNYVV. Texas 7 was identified in the three major Texas sugar beet-growing counties. BDMV was identified in four Texas counties and one New Mexico county. This is the first report of BDMV in New Mexico. No soil samples, including those collected directly around beets positive for BDMV, were positive for BDMV. BDMV is probably not a soilborne virus.

**HEIDEL, G. B., C. M. RUSH, T. L. KENDALL, and S. A. LOMMEL. 1993. Partial characterization of a soilborne sugar beet virus in Texas. 27th Bien. Mtg. Amer. Soc. Sugar Beet Technol., Anaheim, CA, March 3-6, 1993.**

Texas 7 is an unnamed soilborne sugar beet virus that was reported in Texas in 1988. It is morphologically similar to beet necrotic yellow vein virus (BNYVV) and is transmitted by *Polymyxa betae*. BNYVV and Texas 7 differ serologically. Foliar symptoms in sugar beets can include broad chlorotic areas along the veins. Leaves are not always symptomatic. Characterization studies were initiated to gather preliminary information on morphological, physiochemical and biological properties. Particle lengths fall between 50 and 300 nm, with more frequent values occurring at 50, 100, 210 and 290 nm. Coat protein molecular weight was estimated at 24 kDa by SDS-polyacrylamide gel electrophoresis. RNA was separated by formaldehyde gel electrophoresis. Four RNA species of approximately 6.6, 4.4, 1.2 and 1.0 kb were observed. Texas 7 RNA 1 and RNA 2 are close in size to BNYVV RNA 1 and RNA 2 (6.8 and 4.7 kb, respectively). Texas 7 RNA was applied to an oligo (dT)-cellulose column. Bound fractions were eluted from the column and electrophoresed on a non-denaturing agarose gel. Three polyadenylated RNA species were observed. No serological relationship was observed between BNYVV and Texas 7 in Western blots. Some BNYVV and Texas 7 virus particles were bound by heterologous antiserum in immunospecific electron microscopy. Texas 7 hosts include spinach, *Chenopodium quinoa*, *Beta macrocarpa*, and *Beta maritima*.

**LINDSTEN, K. and C. M. RUSH. 1993. First report of beet soilborne virus in the United States. Plant Dis. Note (In press).**

The furovirus beet soilborne virus (BSBV), first reported in England in 1982, is vectored by *Polymyxa betae* Keskin and has been identified from sugar beet-growing areas throughout western Europe. BSBV is similar in size and shape to beet necrotic yellow vein virus (BNYVV), the cause of rhizomania of sugar beet, but BSBV is less virulent. Sugar beet, the only identified natural host of BSBV, is frequently a symptomless host, and the actual effects of BSBV on sugar beet are unknown. To determine whether BSBV was present in the United States, three to five sugar beet plants were individually transplanted into each of 19 soil samples taken from sugar beet fields in Texas; five from Colorado; four each from Minnesota, Idaho, Nebraska, and Wyoming; and 10 from California. After 1 or 2 wk, bait plants were harvested and tested by DAS-ELISA for BSBV. Root sap was also mechanically inoculated to

*Chenopodium quinoa* Willd., a local lesion host of BSBV. More than 50% of soil samples tested from each state were positive for BSBV. Characteristic symptoms of BSBV also developed on inoculated leaves of *C. quinoa*. This is the first report of BSBV in the United States and confirms that the virus is widespread in sugar beet-growing areas in this country.

**RUSH, C. M., D. E. CARLING, R. M. HARVESON, and J. T. MATHIESON. 1993. Prevalence and pathogenicity of anastomosis groups of *Rhizoctonia solani* from wheat and sugar beet in Texas. Plant Dis. (In press).**

Ninety-eight isolates of *Rhizoctonia spp.*, primarily *R. solani*, were isolated from wheat and sugar beets grown in the Texas Panhandle and typed for anastomosis group (AG). Eighty-nine percent of the 46 isolates from mature beet were AG2-2, 95% of the 45 isolates from wheat were AG4, and most of the isolates (7) obtained from beet seedlings were either AG4 or AG5. Two isolates of binucleate *Rhizoctonia sp.* also were recovered, one from mature sugar beet and one from beet seedlings. Randomly selected isolates from each AG were capable of colonizing wheat, corn, cotton, and sorghum residue saprophytically, and optimum temperature for growth of most isolates was between 20-30 C. In pathogenicity studies, isolates of AG2-2 and AG4 reduced emergence and final stand of sugar beet seedlings, and isolates of AG2-2 caused severe root rot on mature sugar beet. On wheat, none of the isolates reduced emergence, but isolates of AG4 and AG5 caused significant postemergence root rot. Although some isolates of AG2-2, AG4, and AG5 reduced emergence and caused root discoloration on seedlings of corn, cotton, and sorghum, none was highly virulent on these crops. Both isolates of binucleate *Rhizoctonia sp.* were either avirulent or caused only slight root discoloration. Since AG4, the predominant AG of *R. solani* on wheat, was highly virulent to sugar beet seedlings, wheat preceding sugar beets in rotation is not advised.

**RUSH, C. M., R. C. FRENCH, and G. B. HEIDEL. 1993. Texas 7 a possible strain of beet necrotic yellow vein virus. Pages 59-62 In: Proc. 2nd Symp. Intl. Wrkg. Grp. Plant Virus Fungal Vectors, Montreal, Canada, July 25-27, 1993.**

Restriction enzyme analysis, sequencing of PCR products, and Northern hybridization studies were used to evaluate the relationship between beet necrotic yellow vein virus (BNYVV) and an unnamed furovirus from sugar beet designated Texas 7 (Tx7). Using published sequence data from a European isolate of BNYVV, two pairs of primers specific for each RNA species were synthesized. All primer pairs produced PCR products of the expected size with BNYVV samples. With Tx7 samples, a primer pair specific for the 3' end of BNYVV RNA1 also produced a PCR product slightly smaller than that expected for a BNYVV sample. Restriction analysis indicated the Tx7 PCR product was similar to the BNYVV product but contained a deletion of approximately 30 bases near the 3' end. Sequence analysis indicated the Tx7 PCR product had approximately 75% nucleotide and 96% amino acid homology

with the BNYVV PCR product. Northern blots, using labeled BNYVV PCR products specific for each RNA as probes, also indicated similarities between Tx7 and BNYVV. Probes from the 3' end of BNYVV RNA1, 2 and 4 all hybridized with individual Tx7 RNAs but not probes for BNYVV 5' ends or probes for RNA3. However, when labeled BNYVV cDNA was used as a probe, it hybridized with Tx7 RNA3. Likewise, labeled Tx7 cDNA hybridized with BNYVV RNAs. From these results, we conclude Tx7 is very closely related to BNYVV and is possibly a mild strain with a major deletion in RNA3.

**RUSH, C. M., G. B. HEIDEL, R. C. FRENCH, and M. D. LAZAR. 1993. Relationship between BNYVV and an unnamed soilborne sugar beet virus from Texas. 27th Bien. Mtg. of ASSBT, Anaheim, CA, March 3-6, 1993.**

A study was conducted using PCR technology to determine similarities between BNYVV and an uncharacterized furovirus of sugar beet designated TX7. Published sequence data of an European BNYVV isolate were used to design synthetic primers for each of the four BNYVV genomic RNAs. Specific primers and reverse transcriptase were used to synthesize cDNA from extracts from BNYVV- or TX7-infected *Chenopodium quinoa* which was then amplified by PCR. Most primer sets generated specific PCR products from BNYVV-infected samples but not from healthy plants or those infected with TX7. However, one set of primers specific for BNYVV RNA1 amplified cDNA from both BNYVV and TX7. The PCR products were ca. 950 base pairs (bp) for TX7 vs. 1056 bp for BNYVV. The apparent deletion in TX7 is located near the 3' end (near base 6200 of BNYVV RNA1). Restriction analysis of the TX7 product using Dra I, Tha I, Nhe I, and Spe I gave RFLP patterns similar to those predicted for BNYVV. In fact, Tha I and Nhe I digestion patterns of TX7 PCR products were more consistent with the published BNYVV sequence than those of our BNYVV isolate. This suggests a high degree of sequence homology between these two viruses in the region of RNA1 defined by these PCR primers. The results of this and other work in our laboratory, including RNA and coat protein analysis, indicate that TX7 and BNYVV are closely related. We speculate that TX7 may be a mild strain of BNYVV.

**VAUGHN, K. M. and C. M. RUSH. Integration of biocontrol agents with solid matrix priming of sugar beet seed to reduce seedling damping-off. 27th Biennial Meeting of ASSBT, Anaheim, CA, March 3-6, 1993.**

Seed treatment is an attractive delivery system for biocontrol agents. Biocontrol agents *Pseudomonas cepacia*, strain AMMD, and *Gliocladium virens*, strain Cr-4, were used to inoculate sugar beet seed before, during, and after solid matrix priming. Nonprimed seed was also inoculated with both biocontrol agents, and nonprimed and SMP seeds, not inoculated, were used as controls. These ten seed treatments were planted in soils infested with *Pythium aphanidermatum*, *Rhizoctonia solani*, or noninfested soil. The experiment was conducted in growth chambers. Nonprimed

seed treated with Cr-4 caused some phytotoxicity in noninfested soil, but the problem was overcome when Cr-4 was combined with SMP. In *Pythium* infested soil, the addition of AMMD and Cr-4 with SMP reduced postemergence damping-off significantly better than SMP alone and all nonprimed seed treatments, with the exception of nonprimed seed treated with Cr-4. An interaction occurred between AMMD and time of adding the microorganism with SMP. Final stand was significantly increased when AMMD was added during SMP, but not when AMMD was added before or after SMP. In *Rhizoctonia* infested soil, the addition of AMMD and Cr-4 with SMP significantly reduced preemergence damping-off.

**VAUGHN, K. M. and C. M. RUSH. 1993. Preliminary studies on the presence of three sugar beet seedling pathogens from major production areas in the USA. 27th Biennial Meeting of ASSBT, Anaheim, CA, March 3-6, 1993.**

Three major soil-borne pathogens which cause sugar beet seedling diseases are *Aphanomyces*, *Rhizoctonia*, and *Pythium*. Presently in the United States, there are no label fungicides for *Aphanomyces*, but fungicides for control of *Rhizoctonia* and *Pythium* are available. Tachigaren is a systemic fungicide that is effective against *Aphanomyces* spp., *Pythium* spp., and some strains of *Rhizoctonia* spp. This fungicide is developed by Sankyo of Tokyo, Japan, and is labeled for use in most countries in Europe, but not in the USA. We are interested in getting EPA clearance for Tachigaren in the USA. As part of this effort, we are trying to determine the geographical distribution of *Aphanomyces* and other major sugar beet seedling pathogens throughout the major growing areas in the USA. This information will be used in trying to secure a label for Tachigaren. So far, soil samples from Idaho (Nyssa and Nampa factory districts), the Red River Valley (Moorehead & Minn-Dak factory district), and Colorado (Ft. Morgan & Greeley factory district) have been screened. *Rhizoctonia* was predominantly isolated from Idaho and Colorado. Low levels of *Aphanomyces* were also found in Colorado. Soil samples from the Red River Valley showed high levels of *Aphanomyces*, with some *Rhizoctonia* isolated.

## TEXAS 7 A POSSIBLE STRAIN OF BEET NECROTIC YELLOW VEIN VIRUS

C. M. Rush, R. C. French, and G. B. Heidel

In 1988, a virus similar in particle morphology to BNYVV was isolated from Texas sugar beets and designated Tx7 (Liu and Duffus, 1988). Subsequent investigation revealed Tx7 has four distinct polyadenylated RNA molecules of approximately 6.5, 4.2, 1.2 and 1.0 kb (Heidel et al., 1993). Tx7 has a host range similar to that of BNYVV, is vectored by *Polymyxa betae* and frequently is found in the same fields as BNYVV (Heidel and Rush, 1993). Although Tx7 has much in common with BNYVV, it produces symptoms different from those caused by BNYVV on several hosts. Foliar symptoms of Tx7 on sugar beet include a pale yellow discoloration which primarily follows the major leaf veins, mottling, and a slight puckering or distortion. Foliar symptoms can fade or completely disappear from field beets transplanted into the greenhouse, only to reappear later. In such plants, Tx7 can often be detected by ELISA in nonsymptomatic foliage. Tx7 has no obvious adverse effects on root development. On *Chenopodium quinoa*, Tx7 causes diffuse, pale yellow local lesions which may eventually spread along leaf veins. On *Beta macrocarpa* and *B. maritima*, Tx7 causes necrotic local lesions which ultimately develop into systemic infections on *B. maritima* but not *B. macrocarpa*. Because the symptoms produced by Tx7 are similar to those described for RNA3 deletion mutants of BNYVV (Bouzoubaa et al., 1988), studies were conducted to further evaluate differences and similarities between Tx7 and BNYVV. Studies were also initiated to evaluate how certain host plants reacted to dual inoculations with these two viruses.

### Materials and Methods

**Virus maintenance and purification:** Tx7 and BNYVV isolates were maintained in the greenhouse on *C. quinoa* by mechanical inoculation. Procedures for viral purification were similar to those described for purifying sorghum chlorotic spot virus (Kendall et al., 1988). Tx7 isolates used in PCR and hybridization studies were passed through *C. quinoa* four times, while isolates of BNYVV were mechanically transmitted 5-9 times before use.

**PCR studies:** Two primer pairs were made for each specific BNYVV RNA using published sequence data from European isolates (Bouzoubaa et al., 1985; Bouzoubaa et al., 1986; Bouzoubaa et al., 1987). For each RNA, one primer pair matched the 3' end and one the 5' end. Purified BNYVV and Tx7 RNA were used as templates for first strand cDNA synthesis in reverse transcriptase reactions. cDNA amplification was carried out in a 50 µl reaction using 5 µl cDNA, 10 pmol of each primer, 0.2 mM of each dNTP and 5 U *Taq* DNA polymerase in reaction buffer provided with the enzyme (Robertson et al., 1991).

PCR products were visualized after electrophoresis in a 1% agarose gel by staining with ethidium bromide. Products were cut with various restriction enzymes, and observed fragment sizes were compared with predicted values. One product from RNA1, near the 3' end, was sequenced after gel purification and cloning into pGEM3z (Promega).

**Northern blots:** After PCR product identity was verified, radioactive probes were made. PCR products were gel purified and used as templates in second round PCR reactions which included  $^{32}\text{P}$  labeled dCTP. Radioactive cDNA probes were also produced from unfractionated BNYVV and Tx7 RNA. Northern blots were hybridized with probes as previously described (Church and Gilbert, 1984).

**Dual inoculation studies:** Local lesions of Tx7 and BNYVV on *C. quinoa* were macerated in 0.1 M KPB pH 7.5 plus 0.02 M  $\text{Na}_2\text{SO}_3$  and used to inoculate *C. quinoa*, *B. macrocarpa*, and *B. maritima*. Plants were inoculated with each virus independently or with mixed inoculum. Symptom expression was recorded after approximately two weeks, and ELISA tests were conducted to verify the presence of pathogens.

## Results

**PCR studies:** All primer pairs produced expected products in PCR reactions using BNYVV cDNA except the pair specific for the 5' end of RNA3. When Tx7 cDNA was used, only the primer pair specific for the 3' end of RNA1 gave a product close to that expected for BNYVV. Restriction analysis of the Tx7 product, which was slightly smaller than that expected for BNYVV (approximately 1000 vs. 1056 kb, respectively), indicated a high degree of sequence homology. Failure of *ThaI* to cut the BNYVV product indicated the Texas isolate of BNYVV differed slightly from the European isolate from which the sequence data was derived. *ThaI* did cut Tx7 and gave products of the size expected for BNYVV as did *SpeI*, *NheI*, and *DraI*.

Sequence analysis of the Tx7 product indicated 75% nucleotide and 96% amino acid sequence homology with the BNYVV product. The deletion in the Tx7 product first observed after electrophoresis of PCR products was determined to be 30 bases in the noncoding region of the 3' terminus.

**Hybridization studies:** Radioactive probes specific for sequences near the 3' end of BNYVV RNA1, 2 and 4 hybridized strongly with BNYVV RNA and, to a lesser degree, with Tx7 RNA. Neither the specific probe for BNYVV RNA3 nor any probes specific for sequence near the 5' termini hybridized with Tx7, although all hybridized strongly with BNYVV RNA. However, cDNA probes made with an oligo dT primer and nonfractionated BNYVV and Tx7 RNA hybridized with homologous and heterologous RNA, indicating some sequence homology between the four Tx7 and BNYVV RNAs.

**Dual infection studies:** All hosts inoculated with BNYVV developed bright yellow local lesions which eventually went systemic in *B. macrocarpa* and *B. maritima*. *Chenopodium quinoa* inoculated with Tx7 developed diffuse, pale yellow local lesions. *Beta macrocarpa*

and *B. maritima* inoculated with Tx7 developed necrotic spots surrounded by purple halos. The virus eventually went systemic in *B. maritima* but not *B. macrocarpa*. *Chenopodium quinoa* inoculated simultaneously with BNYVV and Tx7 developed a mottled appearance very different from symptoms on plants inoculated with BNYVV or Tx7 alone. When *B. macrocarpa* and *B. maritima* were inoculated with both viruses, the Tx7 symptom phenotype was dominant. Mixed infections did not change systemic reactions of either virus.

## Discussion

Numerous similarities between BNYVV and Tx7 indicate that Tx7 is very closely related to, if not a strain of, BNYVV. They have similar host ranges, exhibit some serological cross reactivity and have coat proteins of similar size. Both are vectored by *P. betae*, and both possess 3' polyadenylated quadripartite genomes (Heidel et al., 1993). To our knowledge, Tx7 is the only recognized furovirus, other than BNYVV, with a quadripartite genome.

Tx7 and BNYVV also have nucleotide sequence homology as shown by PCR and hybridization experiments in this study. Homology exists between all four RNAs, and the degree of homology is greatest near the 3' termini. The greatest molecular variation between Tx7 and BNYVV appears to occur in RNA3. RNA3 of Tx7 is approximately 1.2 kb compared with 1.7 kb with BNYVV. BNYVV PCR probes hybridized with Tx7 RNA1, 2, and 4, but not with Tx7 RNA3. Since BNYVV RNA3 is primarily responsible for symptom phenotype, it is interesting that Tx7, which differs from BNYVV in symptom expression, also differs from BNYVV on a molecular level at RNA3.

There have been numerous reports that wild type isolates of BNYVV possess four full-length RNA species, and that isolates propagated on leaves often possess deleted forms of RNA3 and 4 (Hamilton et al., 1981; Tamada et al., 1990). BNYVV isolates, with deleted forms of RNA3, produce symptoms similar to those produced by Tx7, including diffuse chlorotic spots, necrotic lesions, and an absence of root symptoms (Hamilton et al., 1981; Tamada et al., 1990). Additionally, when "wild type" isolates and RNA3 deletion mutants of BNYVV are inoculated together to *C. quinoa*, the mutant symptom phenotype is dominant (Jupin et al., 1992). In our study, Tx7 symptoms were dominant when Tx7 and BNYVV were both inoculated to *B. maritima* and *B. macrocarpa*.

There is no question Tx7 is very closely related to BNYVV and exhibits numerous characteristics of BNYVV RNA3 deletion mutants. Furthermore, if one uses the criteria suggested by Hamilton et al. (1981) to differentiate viral strains from new viruses, Tx7 should be classified as a strain of BNYVV. If Tx7 is a strain of BNYVV, it is, to our knowledge, the first reported "wild type" isolate with a deleted form of RNA3. However, because of the potential confusion a "mild strain" of BNYVV might create among regulatory agencies, we are withholding our opinion concerning strain designation until further data is gathered.

# **Developing Laboratory Techniques for Rearing the Sugarbeet Root Aphid *Pemphigus betae* Doane**

A Report of Research Sponsored by the  
Beet Sugar Development Foundation, 1993

Project Number 520

by

G. J. Michels, Jr., R. L. Deerberg, and B. J. Thompson

Texas Agricultural Experiment Station  
6500 Amarillo Blvd. West  
Amarillo, Texas 79106

The sugarbeet root aphid, *Pemphigus betae* Doane, is a heteroecious aphid exhibiting two life cycles involving cottonwood trees, *Populus* sp., as its primary host and herbaceous plants such as sugarbeets, *Beta vulgaris* L., as its secondary host. Most damage is done to the sugarbeet when its water and nutrient uptake are interfered with as a result of the aphids feeding on the secondary roots. Both yield and sugar content can be reduced.

Following from our previous research in 1991 and 1992, where a method was developed to rear sugarbeet root aphids in the laboratory, we determined the impact of temperature on the mass increase of sugarbeet root aphids.

The primary objective in this research was to determine at what temperature sugarbeet root aphids exhibited the maximum density increase over a fixed period of time. The results of the experiments were expected to provide optimal growth parameters to scientists who may wish to rear this aphid and also give insights into the temperature regimes in nature where the aphid may rapidly increase in the field.

## **MATERIALS AND METHODS**

A moist, sterile soil mixture contained in petri dishes was used to maintain young sugarbeets about 2 to 4 months old. Four hundred grams of sieved field soil was mixed with 70 ml sterile deionized water, covered, and autoclaved 15 minutes. Beet leaves were removed at the crown and the entire sugarbeet root was used. Beet roots were not subjected to any treatments other than washing 15 minutes with tap water. Working under a laminar flow hood, the sugarbeets were patted dry using sterile paper towels and individually placed in sterile petri dishes containing soil. The plates were wrapped with Parafilm.

Aphids were retrieved from an infested sugarbeet field and transferred directly from infested beets to sugarbeet plates. There were 10 replications of each temperature regime. One newly-born nymph was placed on each sugarbeet, the plates were sealed with Parafilm, and stored in dark incubators set at 5, 10, 15, 20, 25 or 30°C (41, 50, 59, 68, 77, 86°F), depending on the experiment being carried out. The plates remained in the incubators for two weeks. After this time, the plates were opened and all aphids were counted by gently searching through the soil and on the beets themselves. The aphids were separated into nymphs, adults, and alates (winged forms).

Statistical differences between temperature regimes were discerned through Student's *t*-tests for unpaired observations.

## RESULTS

The results of the experiment are found in Table 1 and Fig. 1. Generally, the number of aphids increased as temperature increased, but fell sharply at 30°C.

The results indicate that the picture revealed by this experiment is a distribution of aphid densities for the generation following the founder nymph, with some new nymphs representing a second generation produced by first generation adults.

In regard to separate life stages, there were few to no alate aphids produced, except at 25°C, where one was recovered. This result is to be expected since the time-span of the study was short and the environmental conditions for the development of a dispersal phase were probably not present.

Adults were also usually found in low numbers; however, this again may be due to the time span of the experiment. The adult numbers increased with increasing temperature. In the cooler experiments, the few adults may be attributable to a slowing of the developmental period by the cool temperature. The adults that were found are assumed to represent a new generation of aphids, not the original founder nymph. Therefore, these would have been some of the first individuals from the founder nymph. Significantly more adults were found as the temperature increased from 5 to 10°C and from 15 to 20°C. All other pairs of ascending temperatures were not significantly different. Although there were no significant differences among the 20-25-30°C regimes, there was a dramatic drop off (approx. 5-fold) in adult numbers from 25 to 30°C, indicating that at this high temperature regime, some deleterious effects may begin to manifest themselves.

In all temperature regimes, the nymphs were found in the largest numbers. The patterns of significant differences paralleled the adult densities, with the 20 and 25°C being very similar (less than an average of two nymphs difference), and a substantially less rapid fall between 25 and 30°C. However, as with the adult densities, this fall may indicate a point where the temperature begins to cause aphid mortality.

## DISCUSSION

The experiments conducted to this date in regard to sugarbeet root aphid development in the laboratory have yielded both a workable technique for rearing this pest in a laboratory situation, and also give an indication of the developmental parameters. From our results, we conclude that if our technique is used, laboratory colonies of sugarbeet root aphids can be stored in a temperature range from 10 to 25°C. As the temperature increases, the production of nymphs and adults also increases. Alate forms are not a problem during short time spans, however, after longer storage times, they may develop more rapidly. Additional research should be carried out to determine the effects of temperatures on both the maximum time a colony can survive at higher temperatures, and how long the beet can remain a suitable host. Although our results indicated that the aphids do not do well at 5°C, it would be interesting to see if a colony can be maintained at low densities at these temperatures.

This could be very important to a researcher who would like to maintain a colony in between experiments, when sugarbeet root aphids from the field or fresh sugarbeets are not available.

The results of our experiments may indicate, additionally, where sugarbeet root aphids may be found in the field. As soil temperatures warm in the spring, aphids which have overwintered in the soil may move up in the profile to take advantage of the more favorable temperatures. Conversely, as summer temperatures rise above 30°C (96°F), aphids may again move down in the soil profile. If this movement does occur, it would be very important for non-systemic insecticides to be applied in such a manner that they penetrate far enough into the soil profile to reach levels where the soil temperature is conducive to rapid aphid growth. If insecticides (especially granules) were applied to the surface and not watered into the profile, there is a good chance that they may never reach the depth where most of the aphids congregate.

The results of this laboratory research open a number of other avenues that need to be explored. Longer time periods at constant temperatures would yield definite upper and lower temperature limits. Field studies that correlate aphid location in the soil with soil temperature may be very useful in applying these laboratory results to a practical situation involving chemical control of the sugarbeet root aphid.

Fig. 1. Effects of temperature on sugarbeet root aphid increase.
